In general, in relation to the insane, the ruling idea or illusive opinion characteristic of their disease, considered with respect to the imputability of their actions, ought not to be regarded as an error, but as a truth; or, in other words, their actions ought to be considered as if they had been committed under the circumstances in which the patient believed himself to be. At Brieg a soldier killed a child because he thought he saw the Deity near him commanding him to do it. Dr. Glanwitz, in his report, came to the conclusion that the man should be confined in a lunatic asylum.

"When the question relates to consent to some particular matter, regard must be had to the prevailing idea, inasmuch as upon its truth or falsity depends the reality of the consent. If, for example, in a civil affair, as a contract, we suppose that the contractor would not have given his consent without a previously existing illusion, this idea is looked upon as an error, not imputable to the person concerned. As to the question, whether the results of the act are cancelled or not, this must depend upon what the laws have decided with respect to involuntary errors.

"In practice, it is difficult to decide whether an affair undertaken by a person labouring under madness, with a fixed illusion, is valid or not, on account of the errors likely to result from this fixed illusion. For as long as this person enjoys his rights, it is not the business of another to examine if his act is valid or not. And besides, the person himself neither could nor would acknowledge his error."

From what has preceded, we apprehend how important it is to determine, in cases of permanent illusion, the paramount idea; to know whether it brings on a derangement, more or less complete, of the intellectual faculties; or only prevents the perfect use of the judgment in relation to certain objects; to discover what influence it has, on one side, upon the notion which the patient has of himself and of his relations with his equals, and, on the other, upon his actions in general. When the prevailing error draws with it a total incoherence of ideas, the case approaches to one of imbecility.

"When a patient attacked by madness, with one fixed illusion, has a false notion of himself and of his relations to others, this circumstance ought to be taken into consideration. For in criminal justice actions ought to be regarded as if the person really was in the state and in the circumstances in which he believed himself to be. Thus the crimes committed by madmen fancying themselves kings and princes, ought not to be punished according to their nature and heinousness; the culpability is lessened or destroyed.

"We ought, above all, to have regard to the illusion under which the patient is carried, by his paramount idea, to commit actions which he considers as matters of duty. In religious madness, for example, the acts which a person afflicted with this form of the disease commits, ought still less to be punished; because no kind of human suffering could have any effect upon a lunatic of this description; divine punishment, or the hope of eternal reward, weighs much more strongly upon his mind than the fear of anything within the power of man."

Similar opinions have been advanced in a manner less restricted, by a high legal authority in France. The following observations are understood to convey the sentiments of the advocate-general, M. de Peyronnet, as they were delivered in a process on the "Affaire de Papavoine:"* "The advocate-general," says the report, "proceeds to examine whether every kind of insanity ought to absolve from culpability, and after distinguishing, in the clearest manner, partial from total derangement, sustains and demonstrates that the last can alone extricate a criminal from the penalty of the laws. This reasonable distinction, thus laid down by the public authority, throws the strongest light upon the questions of mental alienation, the most intricate question in medical jurisprudence, which some physiologists have solved in a manner as unfavourable to accusation as injurious to morality, and alarming to society. M. de Peyronnet here cites some passages from Lord Hale. Of these we should prefer to cite the English text, but as the advocate-general has given to some of the expressions a more definite turn, in a manner which displays fully his own way of thinking, we shall crave permission to deviate from our usual course, and cite the exact words of M. de Peyronnet:

"'Il est une démence partiélle et une démence totale: la première est relative à tels ou tels objets. Quelques personnes qui jouissent de leur raison pour certaines choses sont sujettes à des accès d'uné démence spéciale, à tels discours ou tels sujete, où bien elle est en particlle dans ses degrès; telle est la condition d'une foule d'insensés; et surtout des personnes mélancoliques dont la folie consiste la plupart du temps à témoigner des craintes, des chagrins excessifs, et qui cependant ne sont pas entièrement privées de l'usage de la raison. Cette démence partielle *semble ne pas*

* Discussion Médico-légale sur la Folie, &c. par le Docteur Georget. Paris, 1826. See, also, Examen Médical des Procès criminels des nommés Léger, Feldtman, Lecouffee, Jean-Pierre, et Pavoine, &c., par le Dr. Georget. Paris, 1825.

excuser les crimes que commettent ceux qui en sont atteints, *même en ce qui en fait l'objet principal;* car toute personne qui s'arme contre lui-même ou contre d'autres, est jusqu' à un certain point dans un état de démence partielle lorsqu'elle se rend coupable.....Je suis en outre forcé d'admettre qu'il est une importante distinction entre les cas civils et les cas criminels. Dans les premiers, dès qu'il est prouvé que la raison de l'homme est altérée, la loi annulle ces actes, *quoiqu'ils n'aient aucune relation avec les circonstances qui causent sa démence, et qui auraient pu influér sur sa conduite. Mais lorsqu'il s'agit de décharger un homme de la responsibilité de ses crimes, et surtout de crimes atroces, on ne peut point réclamer l'application de cette règle, incontestable pour une question de propriété.*'

"After having laid down principles so precise, so positive, so satisfactory to the jury," continues the reporter, "the advocate-general applies them to the cause." The same writer cites further the following passage, which leaves no doubt as to the views of M. de Peyronnet: "The pretended insanity of the accused is a pretext had recourse to in despair of the cause: certain it is that this derangement cannot have been total; it is likewise proved that it could not be partial, and in this last supposition, if even allowed, *it could not serve for an admissible excuse.*"

M. Georget, possessing much more correct knowledge of the real nature of monomania, or partial illusion, considered the joint opinion of these lawyers as highly objectionable. He expressed his astonishment at the sentiments of Lord Hale. "This writer," he says, "appears professedly to consider property of higher value than human life! There is then no excuse for an unfortunate lunatic, who in a paroxysm commits a reprehensible action, even although it should appear to be the result of his particular illusion! And yet the civil acts of this same individual are to be annulled, although they have no relation to the insane impressions which might have influenced his conduct! And even M. de Peyronnet could cite such maxims as these with approbation; we do not at least find he has objected to any part of them. All monomaniacs, according to this statement, are liable to become criminals in spite of the sixty-fourth article of our penal code, and may undergo the penalties recorded for atrocious offences."

M. Georget has refuted these opinions on grounds which must be conceded by the jurists of all countries, viz. on those of experience and correct knowledge as to the real state of monomaniacs. Such persons, as he has clearly proved, though they reason correctly on a variety of subjects remote from the particular one on which their illusion turns, are yet more fully deranged than they appear to be, and are even liable to display perversities both in feeling and action. Cases like those of Swedenborg and the German professor mentioned by Hoffbauer, very rarely occur. Even in these instances, had we been enabled to follow the individuals affected into private life and to observe their personal deportment, it is almost certain that something would have been discoverable in their moral character and habits different from those of ordinary men. M. Georget's observations have led him to form nearly the same opinion as to the nature of monomania or partial derangement as that which we have expressed in a former part of this work. (See INSANITY.)

The facts of a remarkable case of this description which came out in evidence some years ago before an English court, confirm in a striking manner the character here ascribed to this disease. For a full account of this we must refer to a "Report of the judgment in Dew vers. Clarke and Clark, delivered by the Rt. Hon. Sir John Nicholl in the Prerogative Court of Canterbury. In this it was proved that the individual "in the ordinary transactions of life conducted himself and his affairs rationally; was a sensible, clever man; amassed a considerable fortune by his profession; took good care of his property; and that several of his friends and acquaintance, some of them medical persons, never even suspected that he was deranged in mind." It was stated by those who wished to prove his sanity, that "he was a man of irritable and violent temper, of great pride and conceit, very precise in all domestic arrangements, very impatient of contradiction, entertaining high notions of parental authority, rigid notions of the total and absolute depravity of human nature, of the necessity of sensible conversion, and of the necessity or expediency of confessing to other persons the most secret thoughts of the heart." It was proved that this person, such as he is above described, having a daughter "amiable in disposition, of superior talents, patient under affliction, dutiful and affectionate, modest and virtuous, moral and religious," was in the habit of "tying this daughter to a bed-post, flogging her with the most unmerciful severity, aggravating her sufferings by the application of brine, flogging her repeatedly with a horsewhip, pulling her hair out by the roots, and compelling her to perform the meanest drudgery." It is scarcely necessary to add that the able and enlightened judge before whom the investigation of this case was brought, declared the individual to be "non compos mentis."

If such is in general the real character of partial insanity, and if in cases which come near to the idea usually entertained of this disease, are (when and if they occur) rare exceptions to the general fact, it will be allowed that criminality should be attached with extreme caution to any individual in whose case the existence of insane illusion has been proved, however limited in its extent this particular phenomenon of the disease may appear to be. The same consideration ought to weigh in an equal degree in questions which respect the exercise of personal rights.

The only remaining topic connected with illusion which we shall at present consider, is the subject of *lucid intervals.*

Hoffbauer has well observed that much depends upon the duration of lucid intervals. In some instances these intervals are very short; in others they are of equal length with the periods of disease, and sometimes they last much longer than these periods. In the former case the individual has consciousness of his actual state with relation to external circumstances, but not with relation to his former periods of existence. His life is only, in his view, in insulated fragments; his knowledge of himself is inaccurate and confused. This

observation can only be applied in a more limited manner to cases in which lucid intervals are nearly of equal duration to the periods of disease. We cannot follow M. Hoffbauer into the inferences which he founds upon this observation.

We must likewise take into consideration the circumstance that repeated attacks of disease weaken the understanding, and that, when they are frequently recurrent, the individual generally falls into a state bordering on dementia, in which the remembrance of persons and relations becomes very defective. In such instances it must become a subject of inquiry to what form and degree of MENTAL DEFICIENCY, as before distinguished, his particular case belongs.

In all examinations respecting insane illusions, it will be necessary to bear in mind the well-known fact, that many lunatics display great artifice in evading questions relating to their morbid impressions, even while these impressions are strongly fixed in their minds. Hoffbauer is incorrect in attributing this dissimulation to the supposed fact, that the lunatic during a lucid interval has perceived his hallucination to be absurd. We know that such dissimulation and evasion have been practised in cases in which no lucid intervals have occurred, especially when the lunatic has been frequently interrogated upon the subject of his erroneous convictions. A striking fact, exemplifying this observation, is mentioned by M. Chambeyron.

The statement of what the English law has positively determined with reference to insanity comes within a comparatively short compass. *Lunacy*, when proved to exist, absolves from guilt in criminal cases. "For," as it is observed by Sir Edward Coke, "the execution of an offender is for example, 'ut pœna ad paucos, metus ad omnes perveniat;' but so it is not when a madman is executed; but should be a miserable spectacle, both against law and of extreme inhumanity and cruelty, and can be no example to others. But if there be any doubt whether the party be *compos* or not, this shall be tried by a jury. And if he be so found, a total idiocy or absolute insanity excuses from the guilt, and of course from the punishment of any criminal action committed under such deprivation of the senses: but if a lunatic hath lucid intervals of understanding, he shall answer for what he does in those intervals, as if he had no deficiency. Yet, in the case of absolute madness, as they are not answerable for their actions, they should not be permitted the liberty of acting, unless under proper control; and in particular they ought not to be suffered to go loose to the terror of the king's subjects." (Blackstone, book iv. c. 2 and 3.) The question is, what will be considered as *lunacy*. In the penal code of France, it seems, from M. Georget's statement, that partial insanity is a sufficient plea against responsibility for offences: this we rest upon the sixty-fourth article. It would appear, however, from the passages cited above from Lord Hale, (which, however, the reader ought to compare with the original text of that lawyer,) that partial insanity is not considered in English law as entirely cancelling responsibility for actions, or consequently culpability, or what the Germans more correctly term (*strafbarkeit*) punishability.

It is observed by Professor Hoffbauer, that in cases of partial illusion it is extremely difficult to ascertain how far the influence of the insane error extends, and what trains of thought and acts of the understanding are within or without the limits of its sphere. If this be borne in mind, and it be also fully made known to juries that monomania generally involves a morbid perversion, and sometimes occasions a total change of the moral character of the individual affected, the cases of punishable criminality occurring under circumstances of mental disease will probably be reduced to a very small proportion.

The exercise of civil rights is suspended when a lunatic is proved to be such: he is neither capable of entering into marriage, nor of any other contracts. These disqualifications, however, only subsist during actual derangement: in a lucid interval a lunatic resumes the exercise of personal rights.

The chancellor, on receiving information as to the state of a deranged person, issues a writ "de lunatico inquirendo," and on lunacy being established by the verdict of a jury, appoints committees to take care of the individual as to his person, and to administer his estate.*

2. Of Moral Insanity, in its relation to criminal and civil law.—In the essay on insanity contained in a former volume of this Cyclopædia, we described a form of mental derangement, under the title of moral insanity, consisting in disorder of the moral affections and propensities, without any symptom of illusion or error impressed on the understanding. The question whether such an affection really exists or not is very important in connection with medical jurisprudence, and we find it to be an indispensable duty here to enter upon it and consider it under this relation.

We must first observe that no such disorder has been recognised in the English courts of judicature, or even in general admitted by medical writers in England. By them it has been laid down that insanity consists in, and is co-extensive with, mental illusion. English writers in general admit only that form of insanity which the Germans term *wahnsinn;* they know nothing of moral insanity either as requiring control in the exercise of civil rights, or as destroying or lessening culpability in criminal ones. Thus in a report of judgment issued not many years since by one of the most distinguished lawyers in this country, it is laid down that "insanity is deluded imagination, the substitution of fancies for realities." In the same report we find the following remarks:—

"As far as my own observation and experience can direct me, aided by opinions and statements I have heard expressed in society, guided also by what has occurred in these and in other courts of justice, or has been laid down by medical and legal writers, the true criterion is—where there is delusion of mind there is insanity; that is, when persons believe things to exist which exist only,

* For further particulars as to the modes of proceeding respecting lunatics, see the Appendix to Dr. Cox's work on Insanity, and Paris and Fonblanque's Medical Jurisprudence, vol. i. p. 289 & seq.; also Blackstone, book i. c. 8, s. 18. Item, c. 15, 4. Book ii. c. 19, 1. Book iii. c. 27. Book iv. c. 2, 2.

or at least in that degree exist only in their own imagination, and of the non-existence of which neither argument nor proof can convince them, they are of unsound mind; or, as one of the counsel accurately expressed it, 'it is only the belief of facts which no rational person would have believed, that is insane delusion.' This delusion may sometimes exist on one or two particular subjects, though generally there are other concomitant circumstances, such as eccentricity, irritability, violence, suspicion, exaggeration, inconsistency, and other marks and symptoms which may tend to confirm the existence of delusion, and to establish its insane character."*

The right honourable and learned judge afterwards cites some authorities, both medical and legal, in support of his opinion. The former are principally the sentiments of Dr. Battie and Dr. F. Willis. Dr. Battie says that "deluded imagination is not only an indispensable, but an essential feature of madness."

Dr. F. Willis, in his treatise on mental derangement, which was the substance of the Gulstonian Lecture delivered before the College of Physicians in 1822, thus points out the difference, according to his apprehension, between an unsound and a sound mind:—

"A sound mind is one wholly free from delusion. Weak minds, again, only differ from strong ones in the extent and power of their faculties; but unless they betray symptoms of delusion, their soundness cannot be questioned." "The man of insane mind from disease, having been once compos mentis, pertinaciously adheres to some delusive idea, in opposition to the plainest evidence of its falsity, and endeavours by the most ingenious arguments, however fallacious they may be, to support his opinion."

Lord Coke and Lord Hale are referred to for a similar opinion.

It seems, then, to have been the prevalent judgment both of medical and legal writers in this country, that *delusion* constitutes the essential character of insanity; and hence, unless the existence of this characteristic phenomenon should be proved, it would probably be very difficult to maintain a plea on the ground of insanity in this country, with a view to the removing culpability in a criminal accusation.

We have now to call the attention of our readers to facts and to the opinions of practical men, established upon the ground of experience, which authorize a very different conclusion.

In the first place, we shall take the liberty of referring to the article INSANITY in this work, in which a select number of cases has been given in a brief and condensed statement, and the opinions of some practical writers have been cited, particularly those of MM. Pinel, Esquirol, and Georget.

The German writers, Hoffbauer, Reil, and Heinroth, admit more or less distinctly the existence of moral insanity, or of a mental disease consisting exclusively in undue and morbid excitement of the passions and feelings. In this they appear in part to have been influenced by the opinion of Pinel. Neither Pinel, however, nor the German writers above-named, have assigned to moral insanity so general a description as the truth warrants, nor have they referred to it all the different forms which really belong to it. *Reine tollheit* and *reine melancholie*, simple madness of excitement and simple melancholy, are indeed brought under one category by Heinroth, but with an imperfect conception of their relations. (Störungen des Seelenlebens, th. 2. Formenlehre.)

Hoffbauer defines *tollheit* to be a state in which reason has lost her empire over the passions and the actions by which they are manifested, to such a degree that the individual can neither repress the former nor abstain from the latter; it does not hence result, as he observes, that the person affected may not be in possession of his senses, and even of his usual degree of intelligence.

Hoffbauer points out many varieties of *tollheit*. One of these consists in general excitement and want of the power of self-government. "The individual," he observes, "abandons himself without restraint to the indulgence of all his appetites and passions in the most shameless and unrestrained manner, without regard to decency or propriety."

The writers, then, whom we have cited, admit the existence of a form of madness consisting in excessive excitement of passions, though they have not recognised moral insanity under so general a character as we have ascribed to it. A similar observation applies to MM. Pinel and Esquirol. The former, indeed, adopts the term of *manie sans délire;* he says that persons labouring under this form of disease display at no period any lesion of the understanding, but are governed by a sort of instinctive madness (instinct de fureur), as if the affections alone had sustained injury from the morbid cause—"comme si les facultés affectives seules avoient été lésées." (Traité Médico-Philosophique sur l'aliénation mentale, par Ph. Pinel, sec. edit. Paris, 1809.) These expressions set forth exactly the idea which we have endeavoured to convey, but we wish to render the observation general, and M. Pinel's cases are all instances of persons who were subject to violent attacks of anger or fury. We may, however, perceive that the writers above-named admit as matter of fact the existence of a variety of mental diseases, consisting in disturbance of the active and moral powers. We shall now collect from them and others a few striking examples.

The following instances were published by M. Marc, and have already been cited by more than one continental writer. The facts display, as the author observes, a struggle in the mind of the individual between the instinctive desire which constitutes the whole manifestation of disease, and the judgment of the understanding still unaffected and struggling against it. (Consultation Médico-légale pour H. Cornier, femme Berton, accusée d'homicide, par M. Marc, &c. Chez Roux.)

"In a respectable house in Germany, the mother of the family returning home one day, met a servant, against whom she had no cause of complaint, in the greatest agitation; she begged to speak with her mistress alone, threw herself upon her knees, and entreated that she might be sent out of the house. Her mistress, astonished, inquired the reason, and learned that whenever this

* Report of the judgment in Dew v. Clarke and Clarke, delivered by the Right Hon. Sir J. Nicholl. Lond. 1826.

unhappy servant undressed the little child which she nursed, she was struck with the whiteness of its skin, and experienced the most irresistible desire to tear it in pieces. She felt afraid that she could not resist the desire, and preferred to leave the house." "This circumstance occurred about twenty years ago in the family of M. le Baron de Humboldt, and this illustrious person permitted me to add his testimony."

"A young lady," continues M. Marc, "whom I examined in one of the asylums of the capital, experienced a violent inclination to commit homicide, for which she could not assign any motive. She was rational on every subject, and whenever she felt the approach of this dreadful propensity, she entreated to have the strait-waistcoat put on, and to be carefully guarded until the paroxysm, which sometimes lasted several days, had passed."

"Mr. R., a distinguished chymist and a poet, of a disposition naturally mild and sociable, committed himself a prisoner in one of the asylums of the Fauxbourg St. Antoine." "Tormented by the desire of killing, he often prostrated himself at the foot of the altar, and implored the divine assistance to deliver him from such an atrocious propensity, and of the origin of which he could never render an account. When the patient felt that his will was likely to yield to the violence of this inclination, he hastened to the head of the establishment, and requested to have his thumbs tied together with a ribbon. This slight ligature was sufficient to calm the unhappy R., who, however, finished by endeavouring to commit homicide upon one of his friends, and perished in a violent fit of maniacal fury."

"A servant-maid, twenty-six or twenty-eight years of age, whose menstruation was perfectly natural in every respect, nevertheless experienced at each period a sort of excitement which did not apparently affect her judgment, but which rendered her extremely dangerous, since, without provocation, she menaced every person with her knife, and one day having realized her menaces, she was sent to a lunatic hospital."

Plattner and Etmuller have related several instances of homicidal melancholy, but observe that it consists in mental disorder involving no lesion of the reasoning power or understanding.

The following case, reported by Metzger, has been already cited by several authors. M. Hoffbauer has observed that *it is not a case of delusion; that the individual concerned did not labour under any erroneous idea* impressed upon his understanding, but was only not master of his actions. He was under the influence of excessive pride and impetuosity of feeling.

A Russian colonel came to Königsberg to receive an inheritance, and committed there so many acts of violence, that he was summoned before the tribunal of justice. His conduct before the magistrates was equally unreasonable. He had become so much an object of dread at Königsberg, that nobody would execute any commission for him—the very chimney-sweepers required a guard if sent to sweep his chimneys. At last, after several complaints made against him, he was arrested because he had threatened to stab his landlord with a pitchfork for demanding his rent, and had pursued him with that intent. "In going into the prison, I saw," says Metzger, "an old man with white hair, of a respectable appearance, who received me politely. I inquired first concerning his health. 'I am ill through old age,' he replied, 'and tormented with gout, with the stone, and with the scurvy, evils for which I can have no remedy.' He desired to know who had sent me to see him; I told him it was the tribunal. 'I ought to be judged,' he replied, 'by a French tribunal;' and he pretended that I should find proof of what he said in a writing which he forced me to take. At last I informed him of the reason of his arrest. His eyes then became sparkling, and he said in French, with much volubility, that MM. ——— and ——— were his mortal enemies; that they had several times tried to ruin him; that he had experienced much injustice and oppression on the part of the tribunal; and that they had disposed according to their own will of the inheritance of his brother. Being asked what were his occupations, he replied, 'that he was, as every honest man ought to be, free and content, even in prison; that he amused himself with poetry, and copied verses relating to his real situation.'" The following are the conclusions of Metzger: "Although Colonel L. appears to judge and act rationally in every thing beyond the circle of his false impressions (he should rather have said disordered feelings), yet it is clear, from his conversation, conduct and actions, that pride, passion and suspicion have produced a degree of insanity, which renders him dangerous to society, and makes his confinement necessary."

Reil has given the details of a case which has been cited by Professor Heinroth. (Störungen des Seelenlebens, th. 2. Formenlehre, s. 216.) A countryman, who was in the habit of throwing stones at every person whom he could assail, was at length on this very account taken up and confined in a madhouse. There he behaved with the utmost propriety, gave no indication of disordered mind, of delusion, or violence, and became so active and diligent in his employment, that he was supposed to be perfectly sane, and was dismissed from confinement. On the evening after his return home, as soon as his neighbours, who came to welcome him, had withdrawn, he shut himself up in his house with his wife and children, and murdered them all.

The following instances of propensity to infanticide are given by Dr. Michu. In both cases the individuals were afflicted by the consciousness of their state, confessed it, and recovered without any sinister event.

"A countrywoman, twenty-four years of age, of a bilious sanguine temperament, of simple and regular habits, but reserved and sullen manners, had been ten days confined with her first child, when suddenly, having her eyes fixed upon it, she was seized with the desire of strangling it. This idea made her shudder; she carried the infant to its cradle, and went out in order to get rid of so horrid a thought. The cries of the little being, who required nourishment, recalled her to the house; she experienced still more strongly the impulse to destroy it. She hastened away again

haunted by the dread of committing a crime of which she had such horror; she raised her eyes to heaven, and went into a church to pray.

"This unhappy mother passed the whole day in a constant struggle between the desire of taking away the life of her infant, and the dread of yielding to the impulse. She concealed, until the evening, her agitations; then her confessor, a respectable old man, was the first who received her confidence, who, having talked to her in a soothing manner, advised her to have recourse to medical assistance.

"When we arrived at the patient's house, she appeared gloomy and low, and felt ashamed of her situation. Being reminded of the tenderness due from a mother to her child, she replied, 'I know how much a mother ought to love her child; but if I do not love mine, it does not depend upon me.'

"At Bures, the wife of a butcher, forty years of age, of a nervous constitution, the mother of several children, of a mild amiable character, endowed with good sense, who had always enjoyed good health, experienced anxiety of mind in consequence of the derangement of her affairs, of which her husband was a chief cause.

"One night she had a dream, and thought she perceived a cord, which she tried to seize in order to hang herself. On awaking, she was silent, and had confused ideas which soon fixed themselves in a project of strangling her children. She mentioned to her husband, shedding tears, this dreadful design, and requested that her children and even the knives belonging to the trade might be put out of her way."

M. Esquirol has repeatedly declared his conviction that there exists a species of homicidal madness, in which "*no disorder of intellect can be discovered;*" the murderer is driven, as it were, by an irresistible power; he is under an influence which he cannot overcome, a blind impulse without reason: it is impossible to divine the motive which induces him, without interest or disorder of intellect, to commit acts so atrocious and so contrary to the laws of nature.

The same writer observes that physical or moral causes which can be assigned, often give rise to this disordered state.

"In two cases this affection resulted from the change produced by puberty; in four the propensity manifested itself after the individual had heard the history of a woman who had strangled her infant and separated its head from its body. This principle of imitation is one frequent cause of madness. 'Some individuals,' said M. Delaplace, 'possess, from their organization or from bad example, fatal propensities, which are excited by the description of a criminal action, when it has become the object of public attention. Under this idea the publicity of crimes is not without danger.'

"When the affection has continued for some time, and the individuals possessed with the desire of committing murder have been observed, we have seen that this state is, like the delirium of lunatics, preceded and accompanied by headach, and pains in the stomach and bowels; these symptoms have preceded the impulse to murder, and have become more severe when this dreadful propensity is exasperated." (*Esquirol*, sur la Monomanie Homicide.)

In the following case the co-existence of physical disease could be distinctly traced.

"A peasant, born at Krumbach in Swabia, and of parents who had not very robust health, twenty-seven years old and unmarried, was subject, from nine years of age, to frequent fits of epilepsy. Two years ago his disease changed its character without any apparent cause; instead of a fit of epilepsy, this man found himself from that time attacked with an irresistible desire to commit murder. He felt the approach of this attack sometimes many hours, sometimes a whole day before it seized him. From the moment in which he felt this presentiment, he desired, with earnestness, that he might be tied down, that he might be loaded with chains, to prevent his committing a horrid crime. 'When the fit takes me,' he said, 'I am impelled to kill or strangle even an infant.' His father and mother, to whom he was tenderly attached, would be the first victims of this murderous propensity. 'My mother,' he cries out, with a fearful voice, "save yourself, or I shall be obliged to murder you!'"

The following case was published by Pinel, and affords the most striking example of this "instinctive fury." It likewise furnishes an instance of the homicidal propensity evidently connected with physical disease.

"A man who had previously followed a mechanical occupation, but was afterwards confined at Bicêtre, experienced, *at regular intervals*, fits of rage, ushered in by the following symptoms. At first he experienced a sensation of burning heat in the bowels, with an intense thirst and obstinate constipation. This sense of heat spread by degrees over the breast, neck, and face, with a bright colour; sometimes it became still more intense, and produced violent and frequent pulsations in the arteries of those parts, as if they were going to burst: at last the nervous affection reached the brain, and then the patient was seized with a most irresistible sanguinary propensity; and if he could lay hold of any sharp instrument, he was ready to sacrifice the first person that came in his way. In other respects, he enjoyed the free exercise of his reason; even during these fits, he replied directly to questions put to him, and showed no kind of incoherence in his ideas, no sign of delirium; he even deeply felt all the horror of his situation, and was often penetrated with remorse, as if he was responsible for this mad propensity. Before his confinement at Bicêtre, a fit of madness seized him in his own house: he immediately warned his wife of it, to whom he was much attached; and he had only time to cry out to her to run away, lest he should put her to a violent death. At Bicêtre, there appeared the same fits of periodical fury, the same mechanical propensity to commit atrocious actions, directed very often against the inspector, whose mildness and compassion he was continually praising. This internal combat between a sane reason in opposition to sanguinary cruelty, reduced him to the brink of despair, and he has often endeavoured to terminate by death this insupportable struggle. One day he contrived to get possession of the cutting-knife of the shoemaker of the hospital, and inflicted a severe wound upon himself in the right side of his chest and arm, which was followed by

a violent hemorrhage. Strict seclusion and a strait-waistcoat restrained his suicidal purposes." (*Pinel*, Traité sur l'Aliénation.)

The influence of imitation or sympathy in exciting this strange propensity is illustrated by the results of Henriette Cornier's trial. This was a very remarkable case of infanticide, which underwent much discussion, and became the subject of very general conversation in France. Many females of respectable classes, who were strongly impressed by the relation, and the horror occasioned by it, were seized with a similar propensity. M. Esquirol has detailed the circumstances attending several of these cases, on which he was privately consulted. The facts of Henriette Cornier's history, which is one of the most striking examples of the kind on record, are so remarkable that we shall not consider our comments on this subject to be complete without inserting a brief abstract of them.

Henriette Cornier, femme Berton, aged twenty-seven years, domestic servant, was of mild and lively disposition, always full of gaiety and vivacity, and remarkably fond of children. In the month of June, 1825, a singular change was observed in her character: she became silent, melancholy, absorbed in reverie, and was soon dismissed from her service. She fell gradually into a permanent stupor. Her friends were alarmed, suspected that she was pregnant, but were mistaken: they could never obtain from her any account of the cause of her dejection, though she was frequently interrogated. In the month of September she made an attempt to drown herself in the Seine, but was prevented.

In the following October, the relatives of H. Cornier procured her another employment at the house of Dame Fournier. The change of condition made no abatement in her dejection and profound melancholy.

On the 4th of November, the conduct of Henriette Cornier not having been previously in any way different from her usual behaviour, she suddenly conceived and immediately executed the act for which she was committed.

About noon, Dame Fournier went from home, and told H. Cornier to prepare dinner, and to go to a neighbouring shop, kept by Dame Belon, to buy some cheese. Henriette had frequently gone to this shop, and had always caressed a beautiful little girl, nineteen months old, the child of Belon. On this day she went to the shop and displayed the greatest fondness for the little girl, and persuaded Dame Belon, who was at first rather unwilling, to let her take it out for a walk. H. Cornier immediately took the child with her to the house of Dame Fournier, then empty, mounted the common staircase with a large knife which she took from the kitchen, and stretching the child across her own bed, with one stroke cut off its head. The head, which she held in her hand, she placed by the casement and then put the body on the floor near to it. All these proceedings occupied about a quarter of an hour; during this time Henriette Cornier remained perfectly calm; she experienced no emotion of any kind. Dame Belon presently came to seek for her child, and called Henriette from the bottom of the stairs. 'What do you want?' said the latter, advancing on the corridor. 'I come to seek my child,' said Belon, ascending the stairs. 'Your child is dead!' replied Henriette, with perfect coolness. Belon, alarmed, became more earnest; and Henriette again pronounced the words, 'Il est mort, vôtre enfant!' As Belon forced her way into the room, Henriette took the child's head from the casement and threw it, by the open window, into the street. The mother rushed out of the house, struck with horror. An alarm was raised; the father of the child and officers of justice, with a crowd of persons, entered. Henriette was found sitting on a chair near the body of the child, gazing at it, with the bloody knife by her, her hands and clothes covered with blood. She made no attempt for a moment to deny the crime; confessed all the circumstances, even her premeditated design and the perfidy of her caresses, which had persuaded the unhappy mother to entrust to her the child. It was found impossible to excite in her the slightest emotion of remorse or grief; to all that was said she replied, with indifference, 'J'ai voulu le tuer!' 'I intended to kill the child!'

When Henriette Cornier was brought to trial, a plea of insanity was set up. MM. Adelon, Esquirol, and Léveillé were appointed to visit her and report on the 'actual moral state of the accused.' After several visits, these distinguished physicians declared that they could discover no proof of insanity, yet they were not decided as to the non-existence of such disease. The affair was put off; Henriette Cornier was taken to the Salpétrière. There she was inspected repeatedly by the physicians, whose last report concludes that, "from February 25 to June 3, they had observed in Henriette Cornier merely a dejection of mind, slowness in the manifestation of thought, and profound grief; 2dly, that these phenomena are explained by circumstances, and therefore no proofs of derangement; 3dly, that the opinion as to the question of her sanity is materially affected by facts relating to her previous history. If the allegation is proved that, long previously to the committal, her habits, her whole character, had become changed; that she had become at a particular period dejected, gloomy, taciturn, restless, prone to reverie, and had occasionally attempted suicide, it would seem that her present state is not the result of existing circumstances, since it had lasted a year before the commission of the act, in which case the opinion as to her sanity would be materially influenced."

At the renewal of the trial of Henriette, M. Esquirol and several other physicians were examined. The opinions of the physicians leaned generally towards the real existence of derangement. The advocate-general treated the existence of monomania as a mere figment invented by medical persons for the sake of paralyzing the hands of justice. In the end, the jury brought in a verdict that Henriette Cornier had committed homicide voluntarily, but without premeditation, and she was condemned to perpetual imprisonment, with forced labour, and to be branded with the letters T. P., which sentence she heard without betraying the slightest emotion. It is observed by M. Georget that the judges on this trial evinced reluctance to suffer a clear investigation by physicians of the actual mental state of the accused,

and in other respects exerted an unusual influence towards the condemnation. The public sentiment appears to have been against that of the physicians, and M. Georget was treated with ridicule by the journalists of Paris. Yet it is impossible for any person of sound judgment to read the account of this trial, which is given from official documents, without strongly suspecting that the unfortunate woman who was the subject of it, acted under the influence of an impulse which resulted from disease.*

On the whole it seems to us fully manifest that there is a form of insanity, existing independently of any lesion of the intellectual powers, in which, connected in some instances with evident constitutional disorder, in others with affections of the nervous system excited according to well-known laws of the animal economy, a sudden and often irresistible impulse is experienced to commit acts which under a sane condition of mind would be accounted atrocious crimes. Most of the French writers by whom this affection has been recognised, particularly Messrs. Esquirol, Georget, Marc, and Michu, have termed it monomanie homicide, which is assuredly an erroneous designation, unless the sense of *monomania* is to be changed. That term is always used to express *partial illusion*, or intellectual derangement affecting only a certain train of ideas; whereas, in connection with the homicidal impulse now under consideration, there is confessedly no delusive opinion impressed on the belief, and the intellectual faculties are wholly unaffected.

It must be allowed that instances may and do occur in which the discrimination would be difficult between manifestations of insanity and acts of a criminal nature, and that this difficulty would be increased by the admission of a form of insanity free from hallucination or illusion. For the distinguishing characters of this form of insanity we must refer to the article already cited, and to this we shall add a few particulars, chiefly the observations of M. Esquirol.

1. Acts of homicide perpetrated or attempted by insane persons have generally been preceded by other striking peculiarities of action, noted in the conduct of the same individuals; often by a total change of character.

2. The same individuals have been discovered in many instances to have attempted suicide, to have expressed a wish for death; sometimes they have begged to be executed as criminals.

3. These acts are without motive; they are in opposition to the known influences of all human motives. A man murders his wife and children, known to have been tenderly attached to them; a mother destroys her infant.

4. The subsequent conduct of the unfortunate individual is generally characteristic of his state. He seeks no escape or flight; delivers himself up to justice; acknowledges the crime laid to his charge; describes the state of mind which led to its perpetration: or he remains stupefied and overcome by the horrible consciousness of having been the agent in an atrocious deed.

5. The murderer has generally accomplices in vice and crime; there are assignable inducements which led to its commission, motives of self-interest, of revenge, displaying wickedness premeditated. Premeditated are in some instances the acts of the madman, but his premeditation is peculiar and characteristic.

After all it cannot be doubted that there must be instances extremely difficult of discrimination, but this admission does not alter the matter of fact, or change our conviction that disease leads in some cases to homicide, although the faculties of the understanding are at the same time unclouded by any illusion.

We have dwelt more at length on the form of moral insanity which leads to homicide, because in criminal justice it is the most important, at the same time that it is the most striking and characteristic. But there are other instances to which similar observations may be applied. We could adduce facts which prove that other criminal acts, or acts which are criminal when perpetrated by sane persons, have been attempted or committed under circumstances which left no doubt of their resulting from mental disorder, while yet of that disorder illusion formed no part.

The propensity to suicide is in many particulars analogous to the impulse to homicide. It is doubted by many whether suicide is, in general, really an act of insanity, though a verdict of lunacy is generally found in inquests, owing probably to the extreme barbarity of the penal law on suicide. With relation to this subject the following considerations are, as we think, conclusive.

1. The propensity to suicide is very often combined with the impulse to homicide. This has been observed long ago, but the evidence adduced by M. Falret puts the fact beyond all doubt. (De l'Hypochondrie et du Suicide, p. 170, et seq. Paris, 1822.) These impulses are so often conjoined as to prove clearly that the conditions which give rise to one are in close affinity and conjunction with those from which the other originates.

3. Suicide is in a very marked and striking manner hereditary, and this is a strong ground for regarding it as constitutional, or depending on disorder in the state of organic structure. Dr. Rush, Dr. Esquirol, and others have recorded instances of the hereditary transmission of this propensity. M. Falret has collected a variety of observations on the subject, and has concluded that, of all the forms of insanity, that which distinguishes itself by this tendency is probably that which the most frequently becomes hereditary.

3. Like other forms of madness, suicidal insanity prevails most in certain seasons and temperatures. M. Falret says it is most frequent in the summer and autumn. MM. Fodéré and Duglas observed that at Marseilles suicides were most frequent when the thermometer of Reaumur was 22 degrees above zero.

4. Acts of suicide, like those of homicide, are generally preceded by a morbid change in the character and habits of the agent. Individuals

* Discussion Medico-légale sur la Folie par le Docteur Georget, Paris, 1826. See, also, Examen Médical des procès criminels des nommes Leger, &c. par le Docteur Georget, Paris, 1825; and Nouvelle Discussion Médico-légale sur la Folie, par le même, 1828. See, also, Matériaux pour l'Histoire Médico-legale de l'Aliénation Mentale par M. Marc. Annales d'Hygiène Publique et de Médecine Légale. Paris, 1830.

who had been cheerful, active, animated, taking a lively interest in the pursuits of life, in the society of their friends, in their families, became melancholy, torpid, morose, and feel an aversion towards their relatives or most intimate associates, become listless and indifferent. These appearances have often been observed to be the preludes of some attempt at suicide, and have sometimes put the relatives of the individual on their guard, and have led to a prevention of the fatal catastrophe.

5. Suicide is connected in many instances with diseases of structure, or with disorders of the functions of physical life, some of which have been detected by necroscopy, others by observations made before death. This general fact is sufficiently established on the observations made on the subject by Awenbrugger, Leroy, Fodéré, and Esquirol, although we must confess that the same obscurity yet involves the physical causes of suicidal as of other forms of insanity.

6. Like the impulse to homicide, this propensity to suicide is simply a moral perversion, and therefore neither falls within the restricted definition of insanity, which has been the most prevalent one. There is generally no particular illusion impressed on the understanding of the self-destroyer; on the other hand, there is a perversion of the strongest instinct of nature, that of self-preservation. Nature has ordained no other law more universal in its influence than the desire which all animated beings display, and which is indeed the primary principle in the greater part of their actions, and throughout the whole period of their existence, to preserve their existence, and to secure themselves from the influence of circumstances which bring it into danger. It is the characteristic of moral insanity to pervert the natural instincts or propensities, and suicide displays the most signal of these perversions.

Under the head of *moral insanity* we have adverted to a form of disease of which the principal or sole manifestation is a propensity to break and destroy whatever comes within reach of the individual; in short, an irresistible impulse to commit injury or do mischief of all kinds. This propensity is observed in cases in which it is impossible to discover any motive influencing the mind of the person who is the subject of it. No illusive belief, for example, can be detected, that the lunatic is performing a duty in perpetrating that which manifests his disease. There are, indeed, cases of a different description in which this illusion is the groundwork of the proceeding, but these belong to another class of mental disorders.

Many lunatics, whose disorder was merely a destructive propensity, have set fire to houses or public buildings, and it is not to be doubted that men have been occasionally executed as criminals for such actions, who, if they had been kept in confinement, would have proved to be insane. Until the existence of moral insanity is distinctly recognised, there will always be a danger of this event ensuing on the trials of mischievous lunatics. Popular feeling is generally excited in such instances against the perpetrator of a destructive act, and this circumstance increases by much the probability of a criminal condemnation.

There are several modifications of moral insanity, and two most decided examples which require the arrangements suggested by Hoffbauer in some cases of imbecility: we allude to the placing of individuals under *curatela*, or guardianship, for personal security, who do not require confinement. Extreme parsimony has induced persons to starve themselves. When an individual would destroy himself through this propensity, which is in some instances the effect of disease, (see INSANITY,) he is sometimes declared a lunatic and sent to a place of confinement. There is no other way of proceeding by which his life can be saved under the existing regulation. But confinement is unnecessary for such a person, who is in no way dangerous to society. If the management of his property—for such individuals are generally possessed of property—could be so settled as to ensure his having the usual supports of life, this would be sufficient. Another case is that of profuse extravagance, and this is the most common. Individuals whose moral character is perverted by disease often become profusely extravagant, and the apprehension of ruin to their families is the motive which induces the latter to take measures with a view to prevent such a calamity. Confinement is more often requisite with regard to cases of this description than those of an opposite one, on account of other manifestations of disorder which are combined with the leading propensity; but there are probably many individuals who are wholly incompetent, through a habit of thoughtless extravagance resulting from disease, to administer their own estates, or manage their domestic affairs, and in whose condition there is yet nothing that requires confinement in a madhouse. Many of these are examples of extreme difficulty as to the proceedings which ought to be adopted. It will be advantageous, however, to the medical persons who may be consulted in such cases, to be fully in possession of the circumstances connected with them, and aware of the difficulties with which they are surrounded, although these difficulties may be almost insuperable.

J. C. PRICHARD.

[Of late years, owing, more especially, to the occurrence of some important criminal cases in England, in which there was question of insanity, numerous essays have appeared on the subject by well-informed observers; and in this country an able and comprehensive treatise has been published expressly on the subject of the forensic applications of insanity, by Dr. Ray, (*A Treatise on the Medical Jurisprudence of Insanity*, 2d edition, Boston, 1844,) which has been most favourably received by the medical and legal professions. His views agree mainly with those contained in the previous article, by Dr. Prichard. The cases of Francis, for shooting at Queen Victoria, and of M'Naughten, (*Report of the Trial of Daniel M'Naughten, for the wilful murder of Edward Drummond*, Esq. By R. W. Bousfield and Richard Merrett, Lond. 1843,) who was tried for the murder of the secretary of Sir Robert Peel, and acquitted on the ground of insanity, gave occasion to numerous essays on the responsibility of the lunatic—the chief of which are those of Dr. Prichard (*On the different forms of Insanity, in re-*

lation to Jurisprudence, London, 1842); Mr. Forbes Winslow (*The Plea of Insanity in Criminal Cases*, Lond. 1843), and Mr. Rumball (*M'Naughten.—A Letter to the Lord Chancellor upon Insanity*, Lond. 1843).

These cases led to a review of the whole subject of Insanity, in its relation to Medical Jurisprudence, in the House of Lords, and to answers from the fifteen Judges to questions submitted to them by the Lords, which were read to the House in the name of all the Judges except one (Mr. Justice Maule) by Lord Chief Justice Tindall, on the 19th of June, 1843.

These answers must be regarded as the then legal opinion in England, in regard to the points submitted to the Judges. The questions and answers were as follows:

Question 1. What is the law respecting alleged crimes committed by persons afflicted with insane delusion, in respect of one or more particular subjects or persons;—as, for instance, when at the time of the commission of the alleged crime the accused knew he was acting contrary to law, but did the act complained of, with the view, under the influence of some insane delusion, of redressing or avenging some supposed grievance or injury, or of producing some supposed public benefit? *Answer*. The opinion of the Judges was, that notwithstanding the party committed a wrong act while labouring under the idea that he was redressing a supposed grievance or injury, or under the impression of obtaining some public or private benefit, he was liable to punishment.

Question 2. What are the proper questions to be submitted to the jury, when a person alleged to be affected with insane delusion, respecting one or more particular subjects or persons, is charged with the commission of a crime, murder for example, and insanity is set up as a defence? *Answer*. The jury ought in all cases to be told that every man should be considered of sane mind until the contrary were clearly proved in evidence. That before a plea of insanity should be allowed, undoubted evidence ought to be adduced that the accused was of diseased mind, and that at the time he committed the act he was not conscious of right and wrong. This opinion related to every case in which a party was charged with an illegal act, and a plea of insanity was set up. Every person was supposed to know what the law was, and therefore nothing could justify a wrong act, except it was clearly proved that the party did not know right from wrong. If that was not satisfactorily proved, the accused was liable to punishment; and it was the duty of the judge so to tell the jury when summing up the evidence, accompanied by those remarks and observations which the nature and peculiarities of each case might suggest and require.

Question 3. In what terms ought the question to be left to the jury as to the prisoner's state of mind at the time when the act was committed? *No answer*.

Question 4. If a person under an insane delusion as to existing facts, commits an offence in consequence thereof, is he hereby excused? *Answer*. If the delusion were only partial, the party accused was equally liable with a person of sane mind. If the accused killed another in self-defence, he would be entitled to an acquittal; but if the crime were committed for any supposed injury, he would then be liable to the punishment awarded by the laws to his crime.

Question 5. Can a medical man, conversant with the disease of insanity, who never saw the prisoner previous to the trial, but who was present during the whole trial, and the examination of all the witnesses, be asked his opinion as to the state of the prisoner's mind at the time of the commission of the alleged crime, or his opinion whether the prisoner was conscious, at the time of doing the act, that he was acting contrary to law? or whether he was labouring under any, and what delusion at the time? *Answer*. The question could not be put in the precise form stated above, for by doing so it would be assumed that the facts had been proved. When the facts were proved and admitted, then the question as one of science would be generally put to a witness under the circumstances stated in the interrogatory.

Mr. Justice Maule dissented from this last answer. In his opinion, such questions might be at once put to medical men without reference to the facts proved, and he considered that this had been done, and the legality of the practice thereby confirmed, on the trial of M'Naughten.

A century ago, the doctrine was, that to excuse a man from punishment "he must be totally deprived of his understanding and memory, and not know what he was doing, any more than an infant, a brute or a wild beast,—such a one is never the object of punishment." At the commencement of this century, in the celebrated trial of Hadfield, for shooting at George the Third of England, it was maintained that "delusion, when there is no frenzy or raving madness, is the true character of insanity;" and in order to render the madman irresponsible for crime, it must be shown "that the act in question was the immediate unqualified offspring of the disease." In a few years after, however, the doctrine of "right and wrong" sprang up, which has maintained its ground to the present day; and the jury were instructed to acquit, if the prisoner, at the time of committing the crime, was incapable of distinguishing between right and wrong, and did not consider his act any crime against the laws of God and Nature. The doctrine of right and wrong was forcibly laid down in the case of M'Naughten, by Chief Justice Tindal.

Different interpretations have, however, been given of 'right and wrong;' and, as a practical test, when used in a moral and religious sense, it is inefficient, and always difficult to be established. According to the fifteen judges, *right* and *wrong* would seem to mean *lawful* and *unlawful*. "Before a plea of insanity should be allowed," they say, "undoubted evidence ought to be adduced that the accused was of diseased mind, and that at the time he committed the act he was not conscious of right and wrong;" and they add, "Every person was supposed to know what the law was, and therefore nothing could justify a wrong act, except it was clearly proved that the party did not know right from wrong." Yet numerous cases are on record in which unquestioned madmen have been clearly aware of the illegality of acts they have committed. An intriguing, unruly,

vicious madman was detected with a piece of iron, which he had contrived to shape like a dagger: into this iron he firmly fixed a handle. This weapon was taken away from him. He immediately became excessively abusive, and was placed under restraint. After this he was more violent, and uttered the most revolting imprecations. In a fit of fury he exclaimed to the keeper, "*I'll murder you yet. I am a madman, and they cannot hang me for it.*" When Martin set fire to York Minster, a conversation took place among the inmates of a neighbouring mad-house in relation to the occurrence. The question discussed was, whether Martin would suffer the extreme penalty of the law for the crime. Various were the opinions expressed. In the midst of the conversation, one patient, apparently as mad as the rest, exclaimed: "He (Martin) will not be hanged —of course he will escape." "For what reason?" asked several voices. "They cannot hang him," replied the lunatic, "because he is mad,—he is one of ourselves." (Winslow, *Op. cit.* p. 16, and Guy, *Principles of Forensic Medicine*, Part 2, p. 255, Lond. 1843.)

A recent writer (*British and Foreign Medical Review*, July 1843, p. 108) after objecting to these tests, that they do not answer the purpose intended, and that "a man may know that the act of murder or incendiarism, which he is perpetrating, is wrong, that it is an evil, wicked, and illegal act, and yet be a homicidal monomaniac," suggests that the true and only test of responsibility is, "whether or not the individual had at the time *any power of control over his actions?* and this is probably the best single test; still its application is environed with the same difficulties as the others.

The most atrocious crimes are sometimes committed by persons, the unsoundness of whose intellect had not been previously suspected. A man of the name of Steinberg killed his wife and four children, at Pentonville, near London, in 1834; another, of the name of Staninought, a respectable tradesman, killed his son in 1835; another, Lucas, destroyed his children in 1842; and numerous cases of the same kind might be cited, where there were no previous symptoms of insanity, nor any obliquity of the *moral*, to justify interference. They were cases of homicidal impulse, suddenly arising, and destroying all control on the part of the unfortunate agent; and the fact, that, in most cases, the victims were nearly allied, and previously perhaps dear to the destroyer, assimilate them to those of ordinary insanity, which is apt to be directed towards individuals most closely connected with the insane.

Another difficult case is, where eccentricity or waywardness has existed in an individual, or where insane delusion has been manifested on some unimportant subject, whilst on all others the mind may have been apparently sound,—whether such aberration ought to free from responsibility for criminal acts not connected with such delusion? The usual course in courts of law has been to regard such persons as entirely responsible; yet it is obvious that the rule ought not, in justice, to be held absolute; otherwise cases of homicidal monomania, like those referred to above, must be treated as if they had occurred in those of sound mind, which, even if considered expedient, would scarcely be just. Mr. Chitty (*A Practical Treatise on Med. Jurisprudence*, Amer. edit. Philad. 1835) refers to the case of a lady, who consulted most of the eminent physicians in London on the subject of a piece of wood, which she thought was constantly burning in her throat, and whose mind on every other subject was sound; and we have daily examples of the strangest hallucinations in the hypochondriac. The writer, within the last few years, has attended three persons, who believed that they had a living snake in the stomach, and who could not be persuaded to the contrary. Two of them were engaged in business, and managed all their affairs with their wonted judgment. Suppose, then, that a crime had been committed by any one of these persons, ought he to suffer the penalty of the law? Humanity and justice would certainly suggest that the hallucination indicated an unsoundness of mind, which *might*, under adequate exciting causes, be exhibited suddenly under other forms.

There would be less difficulty in this matter, when a verdict of insanity is rendered in these cases, were the community adequately protected against subsequent outbreaks of a similar character. It not unfrequently happens, however, that medical testimony is adduced in favour of the insanity of a prisoner, when the testimony of the same witness could be easily, and perhaps properly, obtained to show, that at the time of trial, the prisoner was perfectly sane: hence, according to the laws of most, if not all of the States, it is a matter of no great difficulty for one who has escaped punishment on the ground of insanity at the time of committing the offence, to procure, soon after the trial, his discharge from prison under the certified plea of entire restoration; and thus to be left at full liberty to pursue his perilous volition, should fresh causes revive the homicidal impulse. "There are some," says a recent writer, (Guy, op. cit. p. 265,) "who argue, that to confine the insane for life is an injustice, inasmuch as the disease under which they labour may be completely cured. It is an injustice towards the individual, but the step is demanded by a regard to the public safety; and when all the alternatives are weighed, it will be found to be the least injustice that the case allows of. The practical question is this: what amount of injustice are we willing to inflict on the individual in order that society at large may be protected? If the public safety requires that the homicidal monomaniac should be put to death, let the principle be boldly proclaimed and acted on; but if, on the other hand, this seems too great a sacrifice, and too glaring an injustice, we must be content to confine him for life, to prevent the possibility of future mischief. This degree of injustice to the individual a regard to the public safety will justify. Nor is there any good reason to fear that, by exempting the madman from the punishment of death, we shall weaken the hold which the law has on the man of sound mind; for in order that he may escape death, he must successfully feign insanity—a task of no ordinary difficulty—and if he succeeds, a perpetual sacrifice of liberty awaits him. It is not likely, therefore, that society will suffer any injury from the adoption of the course here advocated;

and we may perhaps find, that it gains something by openly attributing to disease some of the most revolting crimes which degrade and debase our common nature."

There is great force in these views; yet the mind revolts at the idea of a person being executed, who under a homicidal impulse has taken the life of another, as in the cases referred to above, where the atrocity of the act was the greatest, and perhaps the sole, evidence of the existence of the mental unsoundness.

In regard to the nature of the testimony relied upon in cases of insanity, and the mode of judging of the same, there is much room for animadversion. Too great weight appears to be given to medical testimony in such cases. It has always been the expressed conviction of the writer, that medical men are no better judges of the existence of mental alienation, than well-informed and discriminating individuals not of the profession. The only advantage, at least, which they can be presumed to have, is from the constant habits of observation and discrimination which the practical exercise of their profession requires. Yet for no other reason than that they belong to the medical profession, inferior men, whose judgments on other subjects would be contemned, are often relied upon to establish the existence or non-existence of a mental condition which demands the most rigid and careful scrutiny. A modern able writer, (*Brit. and For. Med. Rev.* July, 1843, p. 110.) thinks it essential for justice "to abolish medical testimony as it is at present given on trials for crime, where insanity is the plea." "Questions of this important nature," he adds, "should be referred to a board of twelve or more competent men: the state of mind of a person accused of crime should not be left to be decided by those members of the profession whom the prisoner or his friends may select for their known support of his case. As to the question of responsibility and punishment, that should be intrusted to the authorities of the law." The whole subject is, as before remarked, surrounded with difficulties; and hence much room is left for the ingenuity of counsel, to act upon a jury generally composed of men who are eminently unqualified for forming any correct judgment on the intricate subject submitted for their decision.

ROBLEY DUNGLISON.]

MINERAL WATERS. See WATERS, MINERAL.

[MOLLUSCUM.—This cutaneous disease, first so called by Bateman, consists of numerous tumours, varying in size from that of a pea to that of a pigeon's egg, filled with an atheromatous matter, which are developed in the substance of the cutis, and are of various shapes—some round or flattened, and having a large base; others adherent by means of a pedicle.

When the disease is in its simple form, it appears to be wholly local; and after having attained a certain degree of development it is apt to remain stationary through life. Occasionally, as in a case described by M. Tilesius, and in others by M. Biett, the whole body is covered with these tumours, which are at times hard and contain no atheromatous matter, (Biett, in *Dict. de Méd.* xx, 137. Paris, 1839.) M. Biett has seen another variety, more especially in young women after parturition, which consists of small flattened tumours, slightly fissured at the top, of irregular shape, and of a brownish or fawn colour; indolent, and occurring more particularly on the neck.

A more singular variety is that described under the name **Molluscum Contagiosum**, of which many cases have been published of late years. (Paterson, *Edinb. Med. & Surg. Journ.* lvi, p. 279; Henderson, *Ibid.* lvi, 213; Jacobovics, Du Molluscum, &c., Paris, 1840; and Wilson *On Diseases of the Skin*, Amer. edit., Philad. 1843.) It is considered to consist of a morbid enlargement and derangement of the sebaceous follicle, rather than of a tubercular affection of the proper texture of the cutis vera, (Wilson, *op. cit.*), and is characterized by the presence of round, hard tubercles, which are smooth and transparent, and when pressed pour out, from an orifice on their summits, a little opaque or milky fluid. The affection is uncommon,—several of the most experienced dermatologists having seen no case of it. M. Biett affirms (*Op. cit.*) that no case has been observed in France. It is communicable, and is accompanied by tumefaction of the glands, and, occasionally, by so much constitutional irritation as to gradually destroy the patient.

The causes of Molluscum are unknown, and the treatment is unsatisfactory. In simple Molluscum,—the first variety, no mode of management has been of much service; in the variety described by M. Biett, a strong solution of sulphate of copper has dispelled the tumours. In the contagious variety, eutrophics have been prescribed, especially arsenic, and external agents been applied with the view of exciting the tumours to inflammation. The liquor potassæ, and the solid nitrate of silver, have been used with this view.

Dr. R. Paterson is inclined to look upon internal remedies in general as too tedious, "when the local ones can be applied with so little pain to the patient, such surety to the destruction of the tumour, and in so much shorter a space of time."

ROBLEY DUNGLISON.]

MORTIFICATION. The term mortification is generally employed in this country to express that state which has been induced in a part of the body by the complete and permanent extinction of its vital properties. On the continent, however, the term *gangrene* is employed to signify the same state; whilst in England it is more commonly used to denote the incipient stage of mortification: a state of a part in which there is a diminution, but not a total extinction of the vital properties; in which the blood is still supposed to circulate in the larger blood-vessels, and the nerves to retain a part of their sensibility; the complete cessation of circulation and an entire want of sensibility characterize the second or last stage of mortification, which is called *sphacelus*, whether the dead part has or has not become putrid, whether it has been separated or not from the living parts. Again, some pathologists confine the term gangrene to the death of the *superficial* texture of parts, and particularly of the soft parts; and sphacelus, to the death of the *whole substance* of an organ, as of the soft parts and bones at the same time.

Other denominations have been given to this pathological state, founded on particular conditions of the affected part, which have been observed to precede or accompany mortification. Thus, we have what is called *hot gangrene*, or that which is preceded or accompanied by inflammation; and *cold gangrene*, or gangrene without inflammation. We have also *humid gangrene*, from the affected part containing a greater or less quantity of decomposed or other fluids; and *dry gangrene*, when these fluids are not present, or only in very small quantity, and which being frequently the case in gangrene affecting the external parts of old people, has, on that account, also been named *gangræna senilis*.

Although some of these distinctions are, no doubt, of considerable importance, some of them are extremely vague and improper, and much less deserving of our attention than the conditions of the part affected with mortification, and the causes by which this state is induced.

Before entering upon the general considerations which present themselves on the several kinds of mortification which occur, it may be well to remark that we shall employ the terms *gangrene* and *sphacelus* as they are generally employed in this country; that of *mortification* constituting the generic sign of the disease of which they indicate particular stages. Although, however, the adoption of these two terms is founded on the differences which exist between the morbid conditions to which they are applied, and their use is necessary to distinguish a state of a part yet susceptible of recovery from one that is not, we shall find that it is by no means easy to determine—even when external parts are the seat of mortification, and, consequently, when any of the phenomena of this disease are capable of being submitted to actual observation—whether the vitality of the affected part be partially or wholly destroyed. It is, perhaps, on this account, and as expressing also a favourable doubt, that the term gangrene is much more frequently employed than that of mortification or sphacelus.

As the descriptive characters of mortification were originally drawn from the appearances which this disease presents when it attacks the external parts of the body, they have ever since been employed by the pathologist as the means of enabling him to detect it in internal organs after death. It may, however, be fairly questioned whether the application of the term mortification has not been too restricted; and whether parts deprived of their vitality and separated from the living tissues should not be designated by the same appellation as those which, similarly situated, differ from them only in point of colour, and perhaps smell. Softening of the cerebral substance, of the mucous and frequently of the serous membranes, constitutes a state of positive death; but the softened substance, in these instances, presenting neither the peculiar colour nor odour of external parts when mortified, it has been considered necessary to distinguish softening from mortification, by a term expressive of its principal character—that of softness. We shall, therefore, treat in this article only of those states which are usually comprehended under the term mortification.

Considered in a general point of view, and in relation to the causes by which it is produced, or the morbid conditions of the part in which it occurs, we find that mortification takes place in a variety of ways, and under very different circumstances. A knowledge of these facts suggests the propriety of arranging the several kinds of mortification under the three following heads:—

1. Mortification from cessation of the circulation.

2. Mortification from the violent operation of mechanical, chemical, and physical agents.

3. Mortification from the deleterious influence of certain poisons.

Cessation of the circulation in a part of the body may be produced in the three following ways:—by inflammation; by mechanical causes which obstruct the passage of the blood; by local or general debility.

1. Mortification from Inflammation.

There is no tissue or organ of the body which may not become affected with mortification as the immediate or mediate effect of inflammation. Mortification is, however, much more frequently observed in those organs in which the vascular system predominates, or in which an inordinate accumulation of blood is readily produced, on account of their great sensibility and their direct exposure to the influence of those causes which give rise to inflammation. Hence the reason why gangrene and sphacelus occur more frequently in the skin and cellular tissue, mucous membranes and lungs, than in the other tissues and organs of the body, as immediate effects of inflammation; and why they are so rarely observed in serous and fibrous tissues, which contain few or no blood-vessels.

Not only is mortification rarely observed in these latter tissues, but it may also be said never to occur in them as an immediate effect of inflammation, for they are never found in a state of gangrene or sphacelus, unless the cellular membrane with which they are in contact, and from whose vascular system their nutrition is derived, has previously been diseased. Such also is the case in caries, (death of bone,) as a consequence of inflammation of the periosteum and medullary membrane.

These circumstances enable us to explain why, in certain cases, mortification takes place in one tissue and not in another, although the inflammation by which it is preceded is the same in kind, degree, and duration. There are, however, many other circumstances of perhaps still greater importance, the single or conjoint operation of which favours in a most remarkable manner the termination of inflammation in gangrene and sphacelus.

1. Certain diseased states of an organ or tissue—of the solids in general, or of the blood in particular—are circumstances which, while they predispose to inflammation, give at the same time to this pathological state a peculiar tendency to terminate in gangrene or sphacelus of the parts which it affects. Thus, chronic inflammation of a portion of an organ, particularly when accompanied by induration and obstructed circulation of the affected part, is not unfrequently followed by gangrene and sphacelus; and still more frequently is this the consequence of an acute attack of the same disease, either in that portion of the organ previously modified, or in a contiguous portion of it, through

the medium of which the nutrition of the former was derived.

2. In like manner, when inflammation occurs in an organ in a state of congestion, depending on the presence of an obstacle to the return of the venous blood, the danger of its terminating in mortification is increased in proportion to the extent of the obstacle or the degree of congestion to which that obstacle has given rise.

3. The state of general debility which prevails at the termination of protracted fevers, or during the first period of convalescence, is well known not only to favour the development of inflammation, but to give to this disease a great tendency to terminate in mortification.

4. The influence which a diseased state of the blood exercises in the production of mortification is well exemplified in scorbutus; local inflammation in this disease, even when it has only arrived at the congestive stage, frequently terminating with great rapidity in gangrene and sphacelus.

The termination of inflammation in either of these states is likewise regarded by many to depend much on the nature of the cause by which the inflammation has been induced. It would, however, be more correct to say that the termination of inflammation in gangrene or sphacelus depends on the nature of the change which follows the immediate operation of such a cause on the organ in which inflammation afterwards take place.

It is true that, independently of any peculiarity of constitution, a mechanical stimulus will produce inflammation very different in its external characters, intensity, extent, duration, and mode of termination, from that which follows the operation of a chemical agent or certain poisons. But, were we to attribute these differences solely to something peculiar in the nature of the exciting cause, we should find it impossible to account for the various phenomena by which they are accompanied. For, in one case, the inflammation may be intense, and the gangrene by which it is followed comparatively slight in degree and limited in extent; in another, it may be mild or imperfectly developed, and yet gangrene and sphacelus succeed each other to a great extent; and in a third, whether severe or mild, its termination in mortification may take place slowly, or proceed with frightful rapidity. All these varieties, also, are observed, without a corresponding change in the causes by which they are produced; the same cause producing at one time only inflammation, at another gangrene or sphacelus.

Instead, therefore, of seeking in the nature of the exciting cause itself an explanation of these remarkable differences, we must have recourse either to the peculiar change which it has induced in the part which afterwards becomes the seat of inflammation, or to some previous modification of the kind to which we have already alluded; such as a morbid state of an organ, of the body in general, or of the blood in particular.

The above are some of the more remarkable of the circumstances which favour the development of gangrene or sphacelus as a consequence of inflammation: the following are some of those which exercise an opposite influence.

1. The first of these in importance is a perfect state of health, whereby inflammation, instead of terminating in gangrene or sphacelus, as it would have done in an individual less favourably circumstanced, is limited to one or other of its more simple forms, — as the adhesive, suppurative, or ulcerative.

2. The structure and situation of an organ, whereby the increase in quantity of the fluids of nutrition and secretion, which takes place during inflammation, is either entirely prevented, or very limited in degree and extent. All secreting organs or surfaces which possess a free exit to their superabundant fluids, natural or morbid, furnish examples of this kind; as the serous and mucous membranes, which, compared with the testes or breasts, in which the circulating and effused fluids are retained, are rarely the seat of gangrene or sphacelus as the direct consequences of inflammation.

3. The importance of an organ, whereby death supervenes before mortification can take place as a consequence of inflammation. Mortification of the brain and heart seldom or never occurs, unless when it follows inflammation produced by the direct operation of mechanical causes. When it occurs as an idiopathic affection in the brain and heart, the derangement of function by which it is accompanied becomes so great not only in these organs themselves but throughout the whole body, that general death supervenes, before the inflammation has acquired that degree of severity which gives rise to local death or mortification.

General phenomena of Gangrene and Sphacelus. — As the more remarkable changes which take place in the circulation, innervation, temperature, colour, and consistence of a part affected with gangrene or sphacelus, as a consequence of inflammation, are seldom observed unless on the external surface of the body, we shall describe them as they occur in the skin and subjacent parts.

When inflammation is about to terminate in gangrene, the inflammatory redness assumes a darker tint; it becomes deep purple, livid, or almost black; the temperature of the part diminishes, but not always its consistence, which, on the contrary, may be increased, from the presence of accumulated fluids; small vesicles appear on its surface, formed by the effusion of serosity, or serosity and blood, under the epidermis; the sensibility of the part, which, as well as the temperature, was previously increased, is now much diminished, and the seat of the pain which accompanies the inflammation is transferred to the deep-seated tissues in contact with those which have now passed into the state of gangrene.

When these modifications of colour, consistence, temperature, and sensibility, continue to increase, and terminate in sphacelus, the part thus affected assumes a still deeper tint; it becomes of a dirty brown or black colour, sometimes grey, greyish yellow, or greenish. The vesicles or phlyctenæ become more numerous and larger, or the whole of the epidermis covering the sphacelated part may be completely separated and distended with bloody serum, or ruptured from the same cause, and lying in wrinkles in the denuded and discoloured cutis. The skin and cellular tissue beneath the epidermis are swollen and puffy, and crepitate when pressed; or they are soft, and flaccid, and cold, and may be cut, pinched, or

otherwise stimulated, without pain or feeling of any kind being induced: and, lastly, the sphacelated surface emits a strong cadaverous odour.

When these latter appearances present themselves, but more particularly when the peculiar odour of gangrene is perceived, they may be regarded as certain signs not only of complete death of the affected part to a certain depth, but also that putrefaction has already taken place. The local emphysema and fetor of putrefaction produced during life, constitute, therefore, signs of great value in mortification. Their absence, however, furnishes no proof that local death may not already have taken place; for putrefaction or chemical decomposition of an organ may not follow as a consequence of the cessation of those powers by means of which it was enabled to resist the injurious influence of external agents, until some time has elapsed, the length of which will depend on various circumstances, but more particularly on the quantity of fluids contained in the affected organ, and the degree of temperature to which it is exposed.

So long as gangrene continues to spread, the dark-red colour by which it is characterized is diffuse, and loses itself insensibly in the surrounding skin. But when it is about to terminate favourably, the dark-red colour becomes more circumscribed, gradually disappears, and is replaced by a brighter red, which extends over the affected surface, accompanied by a diminution of the swelling and pain. By-and-bye the natural temperature returns, and the healthy characters and functions of the part are restored, without any solution of continuity having taken place.

A similar change of colour is observed to precede the cessation of sphacelus. It appears on the limits of the dead parts in the form of a narrow circle, and announces that adhesive inflammation, the means which nature employs to arrest its progress, has commenced. Ulceration then takes place along the internal border of the inflamed skin, and a separation is thus effected between the living and dead parts, the latter falling off in the form of what is called a *slough*. The loss of substance which is thus occasioned, is either partially or wholly repaired by means of the coagulable lymph which is thrown out on the denuded surface, and which, becoming organized, assumes a membraneous or granular form, according to the nature of the tissue to be repaired, and constituting ultimately what is called a *cicatrix*.

Such are the general characters of mortification produced by inflammation of the skin and subjacent textures. We say subjacent textures, because inflammation of the former, when such as to produce gangrene and sphacelus, is always complicated with inflammation of the latter.

In other tissues and organs these phenomena are, as we have already observed, more or less modified: the differences which they present depending principally on the degree of vascularity and sensibility of the affected organ. Hence the variety observed in the quantity of blood, and the kind and extent of the effusion by which it is followed in inflammatory gangrene and sphacelus; the change of bulk which organs undergo in either of these stages of mortification; the extent to which their temperature and sensibility may be reduced before they become actually dead; and the length of time that elapses from the commencement to this the ultimate effect of the disease. Examples of these varieties will be found in the following details on mortification of particular tissues and organs.

Mortification of particular tissues from Inflammation.

1. Mortification of the Cellular Tissue.—The cellular tissue is not only more frequently the seat of mortification, but is also more extensively and more rapidly destroyed by it, than any other tissue of the body. It presents, likewise, considerable variety in these respects, in different parts of the body; gangrene and sphacelus occurring more frequently in the subcutaneous than in the submucous cellular tissue; in the fingers more frequently than in the toes; in the thigh and arm than in the leg and fore-arm, owing to the one being more exposed than the other to external injury, or other exciting causes of inflammation.

A greater quantity of cellular tissue in one part than in another, whereby the diffusion of the effused fluids is facilitated, and the presence of fibrous envelopes which afterwards prevent their escape to the external surface, contribute likewise to the greater frequency of the disease, and favour its extension and the rapidity of its progress. The most remarkable example of the influence which these circumstances exercise in the production of gangrene and sphacelus of the cellular tissue, is met with in *erysipelas phlegmonodes*.

a. Subcutaneous cellular tissue.—When erysipelas attacks the subcutaneous cellular tissue of the extremities, and although it may at first be limited to a very small space of the forearm, for example, it sometimes spreads with great rapidity over the whole of that part of the limb, extends upwards to the shoulder and neck, and descends along the back, breast, and side. Throughout the whole of this course the muscles, blood-vessels, nerves, and tendons are laid bare, and float in the putrid cellular tissue, and in the serosity, pus, and blood, that are effused during the violence of the inflammation.

Such is the state of the cellular tissue not only in erysipelas phlegmonodes when it occurs as an idiopathic disease, but also when it succeeds to slight wounds or punctures of the arm in blood-letting, and the fingers in dissection. In such cases the cellular tissue appears to be the primary seat of the inflammation, which may either extend in the manner we have described, or be confined to the cellular sheath of the blood-vessels. In the latter case we have frequently what is called phlebitis; the venous circulation is interrupted; the blood ceases to circulate, coagulates, and nutrition not being maintained by the formation of a collateral circulation, gangrene of the extremity follows as an inevitable consequence.

Besides the *diffuse form* of gangrene and sphacelus of the subcutaneous cellular tissue, there is also a *circumscribed form* which is observed in furunculus, common carbuncle, or anthrax. The great accumulation of blood, and the still greater and rapid effusion of serosity which takes place in these circumscribed acute inflammatory affections, produces a state of extreme induration and compression of the cellular tissue, a greater or less

portion of which being thus as if strangulated, dies from want of nutrition, becomes separated from the living parts, and is expelled, in the form of a grey or straw-coloured spongy or pulpy mass, through an opening made in the skin by a similar process, by ulceration, or a surgical operation.

In cynanche parotidea, or mumps, the cellular tissue of the salivary glands is very similarly situated as in carbuncle or anthrax. It is this tissue that is the seat of the inflammation, congestion, and effusion; and being prevented by the unyielding nature of the glandular tissue of the organ from accommodating itself to the increased quantity of the fluids thus poured into it, it soon sloughs, even sometimes before the glandular tissue has undergone any remarkable change of colour or consistence, and before suppuration has commenced.

It may be remarked here that mortification of the adipose tissue always follows that of the skin and cellular tissue, and in fat persons occasions sometimes the most frightful loss of substance.

b. Submucous cellular tissue.—When *diffuse* or *circumscribed* inflammation of the cellular tissue, terminating in gangrene or sphacelus, occurs in internal organs, it presents the same general characters as those we have just now described. In these, however, it never proceeds to the same extent as when it affects the external parts of the body, either on account of the progress of the disease being checked by one or other of the circumstances to which we formerly alluded, or from death taking place at a very early period.

The *diffuse form* of the disease in internal organs is seldom observed except in the pharynx and larynx, either as a primary affection or in connection with erysipelas phlegmonodes of the limbs, face, or neck.

In these situations the sloughing of the submucous cellular tissue is very limited, and always accompanied by a corresponding state of the mucous membrane which covers it. The effusions of albuminous and puriform fluids which take place at the same time, occasion a great increase of bulk, and produce dysphagia, great difficulty of breathing, or complete asphyxia. Hence the frequently fatal termination of the disease before it has passed into gangrene or sphacelus, and which has sometimes been described under the name of serous, albuminous, and purulent œdema of these parts.

Circumscribed inflammation of the submucous cellular tissue terminating in gangrene and sphacelus, seldom occurs as a primary affection. It follows, in general, inflammation of the mucous membrane, but may afterwards proceed to a considerable extent, and occasion sloughing of all the other tunics of the organ in which it occurs, but more particularly those of the intestinal tube: such is a frequent cause of intestinal perforation, and the fatal peritonitis by which it is followed.

c. Sub-serous cellular tissue.—Gangrene of this tissue as a consequence of inflammation is more frequently observed than sphacelus. Neither of them occurs to any great extent, even where this cellular tissue is most abundant, and where it might be called *retro*-serous rather than *sub*-serous, as in the mediastinum, iliac and lumbar regions.

Inflammation assumes a gangrenous termination more frequently in the sub-peritoneal than in the sub-pleural cellular tissue. In some forms of peritonitis, for example, this state is very marked, although not to be detected by ocular inspection. It is only after the peritoneal covering of the intestine has been divided circularly, and the intestine itself is stretched or pulled out, that the diseased state of this tissue becomes visible. When thus treated, the intestine may as it were be *unsheathed*, that is to say, drawn out of its peritoneal covering, the muscular coat now constituting its external surface.

The great facility with which the sub-serous cellular tissue is thus torn in some cases of acute peritonitis, its pulpy softness in some points, and occasionally a certain degree of fœtor, disposes us to believe that these morbid appearances indicate a near approach to it, if not an actual state of gangrene.

In the cavity of the pelvis, and in the iliac and lumbar regions, these appearances are more marked and more easily detected. Not only gangrene but sphacelus of the cellular tissue is occasionally found in these regions; the inflammation which precedes it being sometimes confined to the cellular tissue, at others extending to the peritoneum.

Gangrene and sphacelus of the sub-peritoneal cellular tissue occurs more frequently in the cavity of the pelvis than in any of the other regions which we have named, on account of the number and importance of the organs which it contains.

Chronic and acute diseases of the uterus and rectum, as cancer and phlebitis, extend their ravages to this tissue, and excite gangrenous inflammation.

External violence, also, is not an uncommon cause of a similar state of disease in this situation; and we have known more than one case in which a blow or fall has occasioned, from the supervention of inflammation in the cellular tissue, extensive destruction of the contents of the pelvis, such as denudation and necrosis of a part of the sacrum, gangrene and sphacelus of the neck of the uterus, and perforation of the vagina.

d. Lamellated cellular tissue, or that which separates the larger subdivisions of organs. Gangrenous inflammation of the cellular tissue of muscular, glandular, and other organs, is less frequently observed than the former as a primary disease. It is only in certain of these organs, particularly the muscles of voluntary motion and the lungs, that we can detect with certainty its existence as a primary affection. We shall notice its occurrence in the latter only, on account of the peculiar character of the lesion to which it gives rise in this organ. A distinct layer of cellular tissue separates, one from the other, the numerous lobules of which the lung is composed. Either of these—the interlobular cellular tissue, or the lobules themselves—may become the special seat of gangrenous inflammation.

When a portion of lung is examined, in which the interlobular cellular tissue is alone or principally affected, it presents a number of lines of considerable breadth, of a straw-colour, having the peculiar distribution of the lobules, and formed by the effusion of pus into the cellular tissue by which they are separated. In this stage of the

inflammation, the cellular tissue is either very soft or easily ruptured, and when sphacelus takes place, is converted into a grey pulp, in which one or several lobules float, attached only by a narrow peduncle composed of their respective blood-vessels and bronchi obliterated.

2. Mortification of Mucous Membranes.—Although inflammation of the mucous membranes is not unfrequently observed to terminate in gangrene and sphacelus, such is by no means so frequently the case as was imagined by the older pathologists. Great congestion, some forms of melanosis, and several other kinds of discoloration of this tissue, produced not only during life but after death, were frequently confounded by them with mortification. The mucous membrane of the throat and intestines is more frequently the seat of this disease than that of any other organ.

In the former it is occasionally met with to a limited extent in cynanche tonsillaris and pharyngea, and constitutes the distinctive anatomical character of cynanche maligna or angina gangrenosa, whether it occurs alone or in connection with scarlatina.

In the latter it follows as a consequence of certain forms of acute enteritis, either when the inflammation affects the mucous tissue itself, or its follicular structure at the same time.

In either of these situations the mucous and follicular textures are primarily affected, and may be converted into sloughs of considerable extent, without the submucous cellular tissue being destroyed.

Thus deprived of their vitality, the mucous and follicular textures are, at first, of an ash-grey or straw-colour, and may afterwards become brown or black. They are, however, frequently of the colour of the matter with which they are in contact: the fluid part of which is readily imbibed by the soft, spongy tissue of the slough.

The mucous membrane which surrounds the slough is generally gorged with blood, indicating either a state of great congestion, or gangrene. Its colour, particularly in the throat, is livid or deep purple. When, however, the gangrenous inflammation is confined to the follicles, as those of Peyer (glandulæ agminatæ), and when the greater part or the whole of the follicle has sloughed, little congestion or inflammatory redness may remain. And, besides, if these glands have previously been the seat of disease, as in tubercular phthisis or chronic enteritis, a slight attack of acute inflammation may be sufficient to destroy their vitality, without any remarkable increase of vascularity or redness being found in them to indicate the nature of the destructive cause.

In this, as well as in many other cases of the same disease in other parts of the body, the state of sphacelus must be determined by the colour, consistence, and smell of the part, taken in connection with the other collateral negative evidence, afforded by the absence of any other cause capable of producing such a state.

On the inside of the cheeks, the surface of the velum and amygdala and pharynx, the presence of circumscribed portions of inspissated mucus, or small patches of coagulated albumen or lymph, formed on the surface of the mucous membrane or epithelium, may likewise be confounded with sphacelus. Detached portions of the epithelium may also assume the appearance of sloughs of the mucous membrane.

Gangrenous inflammation of the mucous membrane of the air-passages is by no means common, unless it be accompanied by a similar disease of the pulmonary tissue, in which case it is generally confined to the smaller bronchi. We have, however, seen it follow perforation of the trachea from malignant disease of the œsophagus, and necrosis of the thyroid cartilage, to which we shall refer more particularly afterwards.

The mucous membrane of the genital and urinary organs is seldom affected with mortification, unless it has been previously injured by mechanical causes, as in some cases of stone of the bladder and kidneys, in lithotomy, stricture of the urethra, and difficult labour, by the improper use of instruments, and also the pressure of the head of the child, to which we shall afterwards refer more particularly, as belonging to another division of our subject.

Of these two systems of organs, the uterus presents the most marked examples of mortification as an immediate consequence of acute inflammation. It attacks the internal surface of this organ either immediately or shortly after delivery; is confined to a small portion of it, particularly to that which gave attachment to the placenta; or occupies its whole extent. The colour of the part affected is of a dirty yellowish grey, brown, black, sometimes greenish or bluish; it feels soft or spongy, is easily torn, and is generally covered with putrilaginous fluid substance of a strong gangrenous odour. When this substance has been removed, the surface is generally found to be rough and irregular, from the presence of the remains of the placenta, and more frequently from an exudation of fibrinous matter, which we have sometimes found to cover the whole surface from the fundus to the os tincæ.

The substance of the uterus is sometimes affected in this manner to a considerable depth, but is more frequently only softened, without having undergone any remarkable change of colour. The presence of pus in the fibrous structure of the uterus is seldom observed beyond the gangrened or sphacelated surface, but is frequently met with in the veins and lymphatics. The appearances which we have described as occurring in gangrenous inflammation of the internal surface of the uterus present considerable variety, owing, apparently, to differences in the seat and extent of the inflammation, and the period at which it proves fatal. But as the investigation of these and other circumstances connected with the pathology of this important subject does not come within the scope of this article, we must refer the reader for further information to the articles Puerperal Fever and Uterine Phlebitis.

3. Mortification of Serous Membranes.—The few general remarks which we have made on gangrene and sphacelus of the sub-serous and retro-serous cellular tissue, show that the same morbid states must occur in the serous membrane itself. For as the blood-vessels of this membrane are principally, if not entirely, derived from those of the cellular tissue with which it is in imme-

diate contact, any disease capable of arresting the circulation in the vessels of the latter, must be followed by a similar result in those of the former, the portion of which so circumstanced being soon deprived of its vitality. This is, in fact, the mode in which serous membranes become affected with gangrene or sphacelus. It is not from their being loaded with blood, under the stimulus of inflammation, that they die and are separated, but from the supply of their nutritive fluid having been cut off, on account of the morbid condition of the circulation in the cellular tissue to which we have just alluded, or from this tissue having been destroyed by suppuration, ulceration, or sphacelus. Sloughing of the serous membrane occurs from one or all of these morbid states, the immediate or subsequent effects of inflammation, and is often followed by a solution of continuity which establishes a communication between the serous cavity and that of the neighbouring organ; such as between the cavity of the peritoneum and that of the stomach, intestines, uterus, kidneys, and gall-bladder, or between the cavity of the pleura and bronchi. The contents of these organs are effused into the serous cavities, and excite a degree of inflammation which is seldom equalled either in the rapidity of its progress or the certainty with which it destroys life. The inferior portion of the small intestine is the seat and source of these fatal changes of structure much more frequently than any other portion of the digestive tube, or any other organ of the body. And, besides, sloughing of the peritoneum perhaps never occurs under the circumstances we have already mentioned, except in the situation of the glands of Peyer, or occasionally in those of Brunner. Inflammation of these glands is extremely common in various diseases of the digestive organs, and whether acute or chronic, may give rise to the same fatal result, viz. perforation of the intestine and peritonitis. (See Perforation of Organs.)

The colour of the sphacelated serous membrane is generally of an ash-grey, sometimes ochrey from the presence of bile or blood. It is soft and spongy, and frequently does not present any peculiar smell. Before it separates, the sub-serous cellular tissue around it is frequently seen injected with fine red capillaries; occasionally, also, all the tunics of the intestine are pale, and the accidental opening appears as if it had been made by excision. But the external border of the opening is always smooth, although irregular, whilst on the internal surface of the intestine it is rough or ragged, or presents other marks of being ulcerated.

A dark brown, dark blue, or black colour of the peritoneum, extending over a considerable portion of its surface, has frequently been described by older authors as indicating the presence of mortification of this membrane. These discolorations, however, depend on causes very different from those which give rise to mortification, and the nature of which is particularly noticed in the article Melanosis.

Gangrene and sphacelus of the pleura take place under circumstances very similar to those which produce them in the peritoneum. Sloughing of the pleura is, however, by no means so frequent as that of the peritoneum, as a consequence of inflammation of the sub-serous or pulmonary tissue. This is owing, in the first place, to the pleura pulmonalis receiving a superior supply of nutritive material from the highly vascular tissue of the lungs, as well as from the interlobular cellular tissue with which it is continuous; and in the second place, from its not being so exposed as the peritoneum, when laid bare, to the operation of highly stimulating fluids.

Gangrenous inflammation of the pulmonary tissue is, next to the presence of tubercle, the most frequent cause of perforation of the pleura pulmonalis from sloughing.

The presence of air and other fluids in pneumothorax and empyema have been known, either from their stimulating qualities, or the mechanical distension which they occasion, to produce gangrene and sphacelus to a considerable extent, of both pleuræ; and the violent inflammation which follows some mechanical injuries is well known to produce a similar effect.

Sloughing of the serous membranes of the brain we have never seen as an immediate consequence of their inflammation; nor do we believe that it ever occurs to any extent, unless it is induced by a mechanical cause, such as wounds and blows on the external surface of the head, or the presence of foreign substances in the brain itself. The same may be said of synovial membranes.

4. **Mortification of Fibrous Membranes.**—We have already stated that these membranes become deprived of their vitality, slough, and are separated, only when the cellular tissue with which they are in contact has previously been destroyed. The death of cartilage and bone, as fibrous tissues, takes place in a similar manner,—that is to say, from previous disease of the perichondrium or other contiguous tissue, and of the periosteum. It is, however, worthy of remark, that the vascular system of the medullary membrane, particularly of long bones, may be the primary and chief seat of the disease, which afterwards gives rise to necrosis and sphacelus of the periosteum. We allude here to phlebitis of the medullary membrane, which succeeds to amputation and some external injuries; and, although belonging, in this case, to the province of surgery, it is more immediately connected with medicine, and the duties of the physician, than might, at first sight, be believed. For it is of importance, not only in a surgical point of view, to know that such is the nature of the inflammation which often follows amputation and some diseases of bone, but also as regards the diagnosis and treatment of the diseased states to which it so frequently gives rise in internal organs. Thus, we have not only purulent infiltration in the lungs, liver, brain, &c., but, in some cases, also gangrene and sphacelus, particularly in the two former of these organs, as consequences of phlebitis of the medullary membrane of bone.

5. **Mortification of Muscular Tissue.**—Inflammation of muscular tissue seldom terminates in mortification, unless produced by an injury which affects at the same time other neighbouring tissues. Gangrene and sphacelus of the muscular tissue of the organs of deglutition and digestion, and perhaps of the heart, sometimes accompanies similar states, or severe inflammation of the other tissues with which it is in contact,

but particularly of the cellular tissue. The loss of substance, thus occasioned, of the muscular tissue in a hollow organ such as intestine, becomes afterwards a serious, and, perhaps, irremediable evil; for muscular tissue not being reproduced, a cicatrix, equal in extent to the loss of substance sustained, is formed, which, possessing a contractile property, gradually diminishes in bulk, and ultimately constricts, even to complete obliteration, the cavity of the tube in which it exists. Such instances are not rare in the small intestines after fever, and the writer possesses a delineation of a case in which there were three strictures of the small intestine, through which only a small probe or writing-quill could be passed.

We have not seen a case of gangrene of the heart, unless some forms of softening, to which this organ is liable, are to be regarded as of this nature. (See SOFTENING OF ORGANS.)

Gangrene and sphacelus of arterial and venous tissues may be noticed here, from the functional connection which exists between them and the heart. They are observed more frequently in the latter than in the former tissue, but do not occur in either until after the cellular sheath of the vessels has been destroyed.

When gangrene or sphacelus of the *spleen* is observed, it is found to follow external injury, followed by peritonitis, or, as it is believed by some, a morbid state of the blood, with which it is in general greatly distended, as in severe cases of some intermittent and remittent fevers of marshy countries. The appearances, however, which this organ presents in these fevers is, perhaps, in a great measure owing to putrefaction.

Mortification of particular Organs from Inflammation.

Having pointed out what appears to be the most important of the circumstances observed in mortification of the elementary tissues of the body, we shall now proceed to describe those which present themselves when this disease takes place in organs. In doing so, we shall confine ourselves to the consideration of mortification of what is called the *parenchyma* of organs, or what in more precise language may be called the *compound tissue* of organs,—the result of a peculiar combination of the simple or elementary tissues.

We have already remarked that the frequency of mortification, the extent to which it proceeds, and consequently its severity, are, *cæteris paribus*, in proportion to the quantity of the cellular and vascular elements which enter into the composition of an organ. In this point of view no organ of the body is so conspicuous as the lungs, and in none does mortification occur so frequently, or proceed to such an extent. Being exposed, too, to the direct influence of a great number of those agents which excite inflammation, as well as to the injurious operation of those causes which produce, mechanically or otherwise, great derangement of the circulation in general, the frequency of the occurrence of mortification in this organ is very considerably increased. For these reasons, and because of the characters of the disease being particularly well marked, we shall commence with the description of mortification of the pulmonary tissue.

1. Mortification of the pulmonary tissue, [*Gangrene of the Lung, Necropneumonia.*] — Although inflammation of the pulmonary tissue is extremely common, it does not frequently terminate in mortification. It is, however, highly probable that inflammation of this tissue proceeds frequently the length of the first stage of mortification of gangrene, without our being able to take cognizance of it during life, or, in a great many cases, to detect it after death.

[Of 305 cases of pneumonia, analyzed by M Grisolle (*Traité Pratique de la Pneumonie*, Paris, 1841), not one ended in gangrene; and of 75 cases of pulmonary gangrene, described in the Medical Journals, not more than 5, at the most, according to the same observer, could be fairly pointed out as the sequence of pneumonia.]

At one period of the history of pathological anatomy, mortification of the lungs was recorded as a common occurrence. The fallacy of this statement was pointed out by Laennec, who considered *gangrene* (used by him in the sense in which we have employed mortification) as rather a rare disease; but it is by no means so rare as this distinguished author was disposed to believe. He states, in his work on "Mediate Auscultation," that he had only met with two examples of it in the course of twenty-four years, and that he knew of only five or six cases of it that had occurred in the Parisian hospitals during the same space of time: we ourselves have seen twice the number of cases in the same hospitals, during a period of not more than three or four years.

[The disease is certainly not so frequent as is usually imagined. It does not often occur in private practice, but in eleemosynary institutions, into which those of broken-down constitutions are freely admitted, it is often seen. In the Philadelphia Hospital, in the nine months prior to August 1838, four cases were admitted, all of which terminated fatally. "It is a disease," says Dr. Craigie, "the presence of which it is difficult to distinguish, in the early stages, from that of other diseases of the lungs; its determining causes are totally unknown, and it is not known that in any genuine instance of it the patient has made a recovery."]

When, as a consequence of inflammation, the pulmonary tissue is affected with gangrene, its colour becomes of a deep red, approaching almost to black, whilst its consistence equals that of hepatized lung or liver. When pressed, it breaks down between the fingers like a portion of hepatized lung when similarly treated, but instead of pus, there oozes out from it blood and a dirty white or greenish fluid of the consistence of milk or treacle, having a very disagreeable odour.

When decomposition has taken place throughout the whole of the affected part, or in other words, when the state of sphacelus is produced, the pulmonary tissue seen under the pleura appears sunk beneath the surrounding surface, presents a dirty white, yellowish grey, brown, or greenish black colour, and frequently, when extensive, a mottled aspect, in which all these tints are perceived; it feels flaccid and pulpy, and, when cut into, appears as if converted into a putrid sanies, in which shreds of pulmonary tissue and blood

vessels float or lie detached, and which diffuses around the most insupportable odour of sphacelus.

Complete death of the pulmonary tissue may take place in several points of the same lung at the same time, but in such cases it is limited in extent, and is much more frequently the result of a septic agent than of inflammation. It is when it is confined to one point that it has been found to extend so as to occupy the fourth, the half, or even the whole of a lobe.

In both cases the sphacelated substance may be limited all round by the adhesive inflammation, or it may be confounded with a gangrenous state of the neighbouring tissue. In the first case we have what is called *uncircumscribed* [or *diffuse*], in the second *circumscribed* mortification. The more extensive, however, the state of sphacelus, the more rarely do we find adhesive inflammation to have taken place.

In the circumscribed and multilocular form of sphacelus, we have sometimes found it confined to one, two, or a very limited number of lobules, the line of separation between the healthy and diseased parts being distinctly marked by the interlobular cellular tissue. In this form of the disease, therefore, we are disposed to believe that the gangrenous inflammation commences in, and is confined to, the pulmonary tissue; whereas in the uncircumscribed and diffuse form it attacks both the pulmonary and interlobular at the same time.

The circumscribed and multilocular form of sphacelus just described may have its seat deep in the substance of the lung, or immediately under the pleura. In the first case one or more of the bronchial tubes are perforated, and thus afford an exit to the dead pulmonary tissue, which is gradually discharged by expectoration. In the second case, besides this salutary mode of evacuation of the sphacelated part by perforation of the bronchi, there is another which frequently takes place, and becomes the immediate cause of death, viz., perforation of the pleura. We have already said that sphacelus of the pleura pulmonalis, when a consequence of inflammation, depends on the previous destruction of its sub-cellular and pulmonary tissue, on account of its nutrition being derived from the vessels of these tissues. Sphacelus of either, therefore, is followed by sphacelus of the pleura, which then presents an appearance similar to a portion of skin destroyed by the cautery or caustic potass. When the slough thus formed is separated, or merely ruptured by the pressure of the fluids or air beneath it, a communication is established between the cavity of the pleura and that produced by the destruction of the pulmonary tissue: one of two consequences then follow; viz., acute pleurisy alone, or pleurisy combined with pneumothorax. In the first case the gangrenous excavation communicates only with the cavity of the chest; in the second, with this cavity and the bronchi at the same time. It is this latter condition of parts which enables us to explain the formation of pneumothorax in this disease, although in some rare cases a gaseous product has been found without perforation of the bronchi, and which appeared to have been the product of decomposition.

When circumscribed sphacelus is not immediately followed by a fatal termination, the lung is found some time after to contain a certain number of excavations of an ulcerous character, the nature and origin of which were either imperfectly or not at all understood, until investigated by Laennec.*

[In all the cases of gangrene of the lungs that have fallen under the author's observation, the subjects were addicted to spirituous liquors. The only pathognomonic symptom, as has been observed by Dr. Stokes (*on Diseases of the Chest*, Amer. edit., p. 324, Phil. 1844), is the extraordinary and disgusting odour of the breath and expectoration, which is generally constant, but in some cases may not be readily appreciated unless the patient is made to cough.

The treatment consists in the employment of the chlorinated preparations internally, or of chlorine by inhalation,—in allaying irritation by opium, and supporting the patient by wine-whey and nourishing diet.]

2. Mortification of the Liver. — Mortification of the substance of the liver is an extremely rare occurrence as a consequence of inflammation; so rare is it indeed, that we have not met with a single well-marked case of it in the course of twelve years, during which period the writer has been in the almost daily habit of inspecting the bodies of the dead, and of examining with care every organ of the body. Nor does it appear that it is a more frequent occurrence even in warm climates, where the liver is so often the seat of acute inflammation. "Gangrene," says Annesley, "has been remarked by many writers and teachers as one of the terminations of acute inflammation of the liver; but although we have observed this disease, and made *post-mortem* examinations of it, the number of which has not been exceeded by any other intertropical practitioner, we have never seen a single case of gangrene of this viscus. We are inclined to believe that the appearances which have been taken for gangrene have been merely that black, congested, and softened state of the organ which is sometimes observed in the more acute attacks of disease supervening to congestion, or, at least, this state of the viscus having speedily run into gangrene after the death of the patient; and therefore, if gangrene had actually existed at the time of dissection, it is to be considered as a consequence of death rather than as a termination of the disease."†

3. Mortification of the Kidneys. — Gangrene and sphacelus of the substance of these organs is very rarely met with, unless the exciting cause has been of a mechanical or chemical nature: we shall therefore defer what we have to say on mor-

* See Traité de l'Auscultation Médiate, &c. vol. i. p. 445; and the article Ulceration in this work.

† Annesley on the Diseases of India, &c., vol. i., p. 434. The explanation given by the author of the appearances to which he refers may be correct, that is to say, that they may have been produced after death; but that any disease can "run into *gangrene* after death," is what we cannot admit without confounding together opposite phenomena, and the limits which language has established between them. *Gangrene* being the decomposition of a living tissue, can only take place in a body that is not dead. *Putrefaction* is the term which the author should have employed, and is used in contradistinction to that of gangrene, to denote the decomposition which takes place in dead animal matter.

tification of the kidneys until we come to consider the influence of these agents in the production of this disease.

The *testes* and *mammæ* are occasionally affected with gangrene and sphacelus as the consequences of inflammation or mechanical violence, and both organs are sometimes so extensively destroyed as to be rendered unfit for the accomplishment of their important functions: but as the treatment of mortification of these organs requires the skill of the surgeon, we shall not enter into the description of its pathological characters as it occurs in them.

There now remains to be described, mortification of the *lymphatic* and *salivary glands*, and of the *brain* and *nerves*. In neither of these compound tissues, however, is this disease observed (unless in some very rare instances, and then limited in extent,) as a consequence of common inflammation. The former are not unfrequently affected with this disease, where they are superficially seated, and where they are exposed to the influence of certain putrid and septic substances carried into them by absorption, and to which we shall refer in another place. The latter have seldom presented any traces of gangrene or sphacelus except in cases of external injury, pressure, or ligature.

To render the enumeration of the tissues subject to death from inflammation complete, we may also mention the *teeth*, *hair*, and *nails*. Inflammation of the capsule, bulb, or roots of these bodies, is frequently followed by their decay and entire separation.

State of the Vascular System in Mortification.—Were we to confine our observations to the changes which take place on the external surface of organs affected with inflammation terminating in mortification, as we have done in the preceding pages, we should form a very imperfect idea of the real nature of this disease. In this as well as in every other morbid state, we must look into the interior of the affected organ, examine the several elements of which it is composed; determine the changes that have taken place in each, the order of their succession, and, as far as it may be possible, the influence which they exercise in the production of the various phenomena of the disease. The interesting experiments and anatomical and microscopical investigations which have been made by several distinguished pathologists on this part of our subject, will enable us to give satisfactory information on several of these important points.

When the transparent part of an animal, such as the web of the frog's foot or mesentery of the rabbit, is placed under the microscope, and submitted to the stimulating influence of a mechanical or chemical agent, the capillary vessels of the part, as well as the blood which under these circumstances flows into them, are seen to undergo a regular series of changes, referable to the hydraulic and dynamic conditions of both, and which constitute the pathological state of a part, called *inflammation*.

Without entering into the details connected with this interesting subject, it will be sufficient for our present purpose to state that when inflammation has arrived at what Kaltenbrunner calls its *perfect state*, that is to say, when the capillaries are distended with blood which has ceased to circulate, that part from a deep red soon changes to a dark brown or black colour.

Cessation of the circulation, coagulation, and discoloration of the blood, are the successive changes which announce that the functions of the inflamed part are about to cease. The change of colour which takes place is found to depend chiefly on a corresponding and similar change induced in the blood contained in the vessel of the affected part, or that has been effused during the inflammatory excitement. Soon after the stagnation of the blood, the globules of this fluid are seen to unite, adhere to the internal surface of the vessels, and form a solid dark-coloured mass occupying their whole calibre. The sensibility of the part rapidly diminishes after the coagulation of the blood, although the nerves themselves are not observed to undergo any perceptible change. The coagulation of the blood is also followed by the cessation of absorption, for the most active poisons introduced into a part, the vessels of which are thus obliterated, either produce none of the effects which are peculiar to them, or do so very tardily and ineffectually, in which latter case they may have found their way beyond the obliterated vessels by imbibition. Under these modifications of function, after a certain length of time nutrition ceases in the affected part, the temperature of which sinks to that of external objects. Its consistence diminishes so soon as decomposition commences, and the colour which it assumes varies with the quantity and quality of the fluids it contains, and the chemical changes which these undergo from the action of the gaseous products of decomposition. Death or mortification of a portion of the body succeeding to inflammation, we therefore regard as an immediate consequence of cessation of the circulation, of which we have examples on a large scale, in ligature and spontaneous obliteration of the principal artery of a limb, unaccompanied by the establishment of a collateral circulation.

The state of the vessels, and of the blood which precede the physical signs of mortification, may be regarded as representing that state of a part which we call gangrene. The blood has ceased to circulate, it is even coagulated; the application of artificial stimuli to the neighbouring tissues, furnishes no evidence of their possessing sensibility or contractility. Yet, as under these circumstances we know that actual death may not have taken place, that the blood may resume its fluidity and circulate anew, and sensibility and contractility again return, the state to which we have alluded may properly be regarded as furnishing us with what may be called the anatomical and physiological characters of gangrene,—a state in which the functions of a part are suspended, analogous to that of the whole body in asphyxia, but not destroyed, whether we regard it as susceptible of recovery, or as an intermediate state which separates inflammation from mortification.

When the recovery of a part from the state of gangrene is about to commence, circulation becomes more active all round the circumference of the diseased part; the coagulated blood gradually disappears by the separation of its globules, and their transmission into the neighbouring currents;

absorption is manifested by the more or less rapid removal of the effused fluids, sensation and motion return, and the part is restored to the healthy state.

We have already enumerated the changes which mark the transition from gangrene to mortification. The separation of the dead part takes place within limits fixed by the state of the vascular system. Thus, the line of demarcation between the dead and the living parts does not extend beyond the obliterated vessels; for before adhesive inflammation has taken place, they are found obliterated to a greater or less distance beyond the mortified part. Their obliteration is not necessarily the consequence of the effusion of coagulable lymph. It depends on the plastic property of the blood contained within the vessels, which unites with their living membrane, becomes organized, and thus secures their permanent obliteration.

Obliteration of the blood-vessels, as the cause of mortification of the kind of which we are now treating, is a subject deserving of the most serious consideration both of the surgeon and physician. For it is to this state alone of the blood-vessels in the vicinity of the dead part that immunity from one of the most dangerous consequences of the disease, viz. hemorrhage, is to be ascribed. The presence of coagulable lymph, its organization and union with the parts into which it has been effused, constituting what is called adhesive inflammation, contributes no doubt to prevent hemorrhage during the process of separation of the dead part, or of sloughing. But we are disposed to believe that it is the prevention of hemorrhage from the smaller vessels only that is secured by the adhesive inflammation, while that from the larger ones is prevented by the previous coagulation of the blood contained within them. That it is to the coagulation of the blood in the large vessels of a limb that we must attribute the non-occurrence of hemorrhage after sloughing, is rendered still more obvious from what occurs in some cases of extensive and spreading gangrene, of the inferior extremity for example, and to arrest which it is found necessary to have recourse to amputation. The limb is removed, but the large blood-vessels yield little or no blood; they are, in fact, obliterated by firm coagula. There is no adhesive inflammation present in such cases, and gangrene and sphacelus succeed to the operation, because of the vessels not having been divided above the point at which they were obliterated.

Such is the state of the large blood-vessels which we have found to accompany sphacelus without hemorrhage. When, on the contrary, hemorrhage occurs in this stage of mortification, these vessels are found pervious, and filled with fluid or imperfectly coagulated blood; and the cellular and other tissues are more or less infiltrated with serosity, sero-sanguinolent, and puriform fluids.

Termination of Mortification. — We have already enumerated the most important and conspicuous local effects of mortification of tissues and organs, such as changes in colour, consistence, sensation, motion, temperature, and bulk, to which we might add those of form, in consequence of loss of substance of various extent.

The solution of continuity which follows the separation of the dead part may, if formed in the substance of a solid organ, be followed by ulceration, instead of being repaired by granulation or the organization of coagulable lymph; or it may be followed by perforation, if the solution of continuity takes place in the walls of a hollow organ, as the intestine, or on the surface of a solid organ, as the lungs, — a termination of sphacelus to which we formerly alluded.

When the dead part is separated, and the affected organ is seated internally, it may either be retained for an indefinite period, or it may be almost immediately expelled through the natural passages, such as the bronchi, trachea, intestines, &c. The dead substance is thus sometimes evacuated entire, as in the case of sloughing of a portion of intus-suscepted intestine, and in some rare cases of partial gangrene of the lungs. In parenchymatous organs, however, the dead portion is much more frequently broken down into shreds by a species of maceration in the surrounding fluids before it is ejected, and is then accompanied by a greater or less quantity of these fluids at the same time.

Signs and Symptoms of Mortification.—To determine the existence of mortification of an internal organ is, in the great majority of cases, beyond the power of the physician. The evidence which he is enabled to collect from the modifications which take place in the functions of the affected organ, from the state of some particular system or of the economy in general, is frequently far from being sufficient to warrant him in giving a decided opinion on the existence of this disease. Besides, the derangements of function to which it gives rise are, in some cases, either so slight as not to be recognised, or of such a kind as not to be distinguished from others produced by very different morbid states. Nor can we fix any determinate relation between the extent of the disease and the severity of its effects, such, at least, as are made manifest to us through the medium of functional derangement. These remarks apply equally to both stages of mortification, and to the kind and degree of inflammation by which they are preceded. With regard to the latter, it is well known that mortification, and that too of the lungs, may succeed to inflammation so slight as not to have induced a degree of indisposition sufficient to excite the attention of the patient, far less to induce him to apply for medical advice. In such cases it is sometimes not until sphacelus has taken place, when the presence of a cavity can be detected by means of the stethoscope, and the contaminating influence of the putrid fluids has already commenced, that the unfortunate patient sends for assistance, or finds his way to an hospital.

There are certainly no general symptoms which can be considered as the exclusive effects of either state of mortification. The violence and extent of the inflammation by which mortification may be preceded, may lead us to *fear* such a termination, but cannot enable us to *detect* it when it has occurred, even when those symptoms — sudden prostration and sinking of the powers of life — and to which so much importance has been attached, are present. Inflammation alone gives rise to these fatal symptoms in persons naturally

feeble, and in those in whom innervation and nutrition in general are so modified by previous excess or privation, as to give to diseases, the most insignificant in themselves, that peculiar assemblage of character generally known under the appellation of adynamia.

We have already enumerated, at the commencement of this article, the more common and obvious conditions of organs which, independently of the general conditions which we have just named, favour the production of mortification, when these organs are attacked with inflammation. We refer the reader to what we have said on this part of our subject, as furnishing additional evidence in favour of the opinion we have given regarding the difficulty of determining the existence of mortification by the manifestation of any particular modification of function of the organ in which it has taken place.

Although we reject, as a *sign* of mortification, the sudden occurrence of prostration and sinking of the powers of life in general, succeeding to inflammation, we must nevertheless regard these phenomena as of great and serious import in such cases, inasmuch as they indicate that the progress of the disease is not arrested, and that by means of absorption the system in general has been brought under the poisonous influence of the decomposed and putrid fluids of dead animal matter. These symptoms, which we attribute to the absorption of dead animal matter, are of course common to mortification from inflammation as well as from other causes.

The state of the pulse in persons affected with mortification of an internal organ is very various. If the previous inflammation has been slight, it may not have been much increased in strength or quickness, and may retain this state after the occurrence of sphacelus, and till near the period of dissolution, when it rapidly sinks, and becomes remarkably slow, feeble, and sometimes intermittent. If the inflammatory excitement accompanies the state of sphacelus, the pulse may continue quick, but it is feeble and easily compressed, and always sinks before death. The temperature of the skin is generally morbidly increased at the commencement, but becomes less than natural towards the termination of the disease, when the surface is often cold and covered with a clammy sweat. At the same time the tongue and teeth become covered with sordes, the breath frequently exhales a fetid odour, and there is occasionally singultus, low delirium, and picking of the bedclothes, or a state of stupor terminating in coma; the countenance assumes a cadaverous aspect, and the whole body as well as the evacuations, which are sometimes involuntary, give out the most offensive fumes, impregnated with the stench of dead and putrid animal matter. In this state the patient dies unconscious, and generally without a struggle. These, the general effects of the absorption of the putrid fluids of sphacelated tissues, are not always so conspicuous; nor do they proceed in all cases to a fatal termination with the same degree of rapidity. When they assume the aggravated form just described, life is seldom prolonged beyond the third, fifth, or seventh day. But when they are marked chiefly by a state of prostration, a quick, feverish, and feeble pulse, a hot skin, and an offensive smell of the secretions, the course of the disease may be prolonged to the second or third week, when it terminates as before described: it is only in this form of the disease that recovery has been known to take place.

The odour of gangrene, as it is commonly called, is perhaps the only pathognomonic sign of the existence of mortification. We have alluded several times to the presence of this odour in the breath of the patient and in the secreted and excreted fluids, as an almost constant sign of the contaminated state of the blood in the last stage of mortification. But the gangrenous odour to which we at present allude is that derived immediately from the affected organ, and which may, with few exceptions, be regarded as the only sign of the local existence of sphacelus to which we can attach a positive value. We need hardly remind the reader that it is not, however, present in every case of sphacelus;—that it is only either in those cases in which a communication exists naturally between the external surface of the body and the sphacelated tissue, or in those in which a preternatural communication has been established in consequence of the disease itself, and through which the putrid effluvia are discharged into natural canals, as in perforation of the bronchi and intestines from without inwards; or on the surface of the body, in perforation of the walls of the chest and abdomen in the opposite direction.

We have seldom an opportunity of detecting the putrid odour of sphacelus, unless when this disease occurs in the lungs, the digestive organs, the urinary organs in the male and female, and in the organs of generation in the latter. When present in the breath, it is necessary to discover its source, as it may have its origin in the mouth, pharynx, œsophagus, or stomach, or in the larynx, trachea, or lungs; this may be easily accomplished by submitting each of these portions of the digestive and respiratory apparatus to a separate examination. It may not be unimportant to observe that extensive sphacelus of the stomach, or rather of accidental tissues formed in this organ, may occur, without the eructations with which it is often accompanied, or even the fluids then ejected by vomiting having any the slightest degree of putrid odour: a circumstance which we attribute to the property which the gastric acid possesses of removing the tainted smell of animal substances.

Much importance is not to be attached to this character of sphacelus when perceived in the alvine evacuations. We have already stated that the excreted fluids acquire this particular odour in consequence of the absorption and the subsequent separation from the blood of the putrid animal matter; consequently the presence of this odour in the dejections may be entirely owing to the elimination of these fluids by the mucous membrane of the intestines from the blood. It may indeed be laid down as a rule, that unless this odour in the alvine evacuations be accompanied by the presence of portions of the intestine, or rather of the mucous membrane of the intestine, it cannot be regarded as a sign of sphacelus of this organ. It is chiefly in some forms of chronic dysentery that the odour of putrefaction

and the presence of sphacelated portions of the thickened mucous membrane are observed at the same time in the discharges which accompany that disease. An entire portion of intestine is never discharged unless in intus-susception followed by sphacelus. We shall have occasion to notice this morbid condition afterwards, under the subdivision of the present subject which treats of mortification in consequence of a mechanical obstacle to the return of the venous blood.

With regard to the putrid odour of sphacelus in the fluids discharged from the urinary organs and vagina, it is only necessary to observe that, in the former it always accompanies a turbid, bloody, or puriform state of the urine; and that, in the latter, there is present at the same time a sanious discharge, sometimes containing blood, and sloughs of the mucous and sub-mucous tissues.

The putrid odour is never so conspicuous as in sphacelus of the pulmonary tissue, and when a communication exists between the sphacelated substance and the bronchi. It is conveyed by the expectorated fluids, composed of those coming from the seat of the disease, as well as from the mucous membranes in general. These fluids are sometimes of a dirty grey, brown, or green colour; puriform or sanious; containing sometimes shreds or small portions of the sphacelated lung; and are occasionally streaked with blood. If hemorrhage has taken place, blood alone may be expectorated in greater or less quantity. In sphacelus of this organ, too, there are various physical signs which, with those already mentioned, and particularly the latter, enable us to detect not only the existence of this state, but also its situation and extent, the state of the surrounding pulmonary tissue, and the mode in which the disease has terminated,—circumstances of greater or less importance as regards the prognosis and treatment.

The most important of these physical signs are the following; but we must observe that they are confined to the second stage of mortification, or sphacelus, and that those of the first stage, or gangrene, are in no respect different from those of pneumonia:—so soon as sphacelus has taken place, a loud crepitous rattle is produced, which gradually assumes a gurgling sound, as the quantity of fluids increase, and the sphacelated tissues become separated from the surrounding pulmonary substance, or broken down. The cavernous rattle continues for an indefinite time, and is replaced by pectoriloquism when the contents of the excavation are partially or wholly removed. The resonance of the voice is remarkably distinct and strong in excavations of this kind, particularly when large, and may, according to Laennec, be distinguished from that which accompanies abscess of the lung, from its having nothing of that *floating* kind of sound of the latter, and is rarely accompanied by the *veiled puff*, so common in the abscess.

When the sphacelus extends to the pleura, and the dead portion is separated, thus establishing a communication between the cavity of the chest and that formed in the substance of the lung, we have, besides the signs already enumerated, those of pleurisy and pneumothorax combined with liquid effusion. If at the same time a communication exists between the bronchi and the excavation, there is heard either the *metallic tinkling* or the *utricular resonance*. The crepitating rattle of pneumonia, which is sometimes heard previous to the occurrence of sphacelus, may continue after the occurrence of it, and may, in some measure, serve to indicate the progress of the disease towards a fatal termination. We have never but once had an opportunity of hearing the crepitating rattle where it indicated the return of the pulmonary tissue to the healthy state. The excavation occupied two-thirds of the inferior lobe of the left lung, and the resolution of the disease was indicated, not only by the state of the pulmonary tissue around the excavation, which was crepitant, and did not contain more blood than usual, but likewise by the presence of an organized false membrane, which lined the internal surface of the excavation, a means which, as noticed first by Laennec, seems sometimes to be employed by nature to limit the progress of mortification.

We must again repeat, that with all these signs our diagnosis can never acquire a positive degree of certitude, unless they are accompanied by the putrid odour of sphacelus.

We have already said that the progress of mortification, although in general more or less rapid, is sometimes slow. Laennec speaks of it as existing in a chronic form in the lungs. It is then accompanied with hectic fever, sometimes considerable, but generally less intense than in most cases of phthisis; the skin feels hot, sometimes even disagreeably so, to the hand; and the expectoration and breath are fetid. This state is accompanied by rapid emaciation, and the disease may be readily mistaken for phthisis; more commonly, however, death supervenes before emaciation has made much progress, the disease appearing to have a greater tendency to produce cachexia than marasmus.

We regard the cure of mortification of the lungs as an exception to the rule, and we have certainly not witnessed this fortunate termination of the disease, except in two or three instances, in which it was not very extensive. In these cases, too, the progress of the disease was limited at an early period, no doubt by the obliteration of the blood-vessels, and adhesive inflammation. That such was the state of the pulmonary tissue around the excavations which were found to exist in these cases, we feel convinced, not only from the disease being stationary from the commencement, but from the general secondary symptoms of mortification, viz., those produced by the absorption of the putrid fluids, not having manifested themselves during the course of the disease. It is, however, stated by Laennec, that he has known several patients recover, who, judging from the extent of the pectoriloquism, had gangrenous excavations of great size. In one of those patients there was sloughing of the pleura as well as of the pulmonary tissue, giving rise to a pleurisy, which was not cured till after a period of fifteen months.

Prognosis of Mortification.—The prognosis of this disease, in the last stage, is always unfavourable, because, on the one hand, of its being accompanied by a loss of substance, and on the other because of the affected organ, or the constitution in general, being frequently in a situation

which the resources of our art can neither remedy nor relieve. Our prognosis will, of course, be greatly modified by the circumstances of each case; the extent of the disease, its seat, the state of the affected organ previous to its occurrence, the age and constitution of the patient, and the situation in which he was placed previous to the attack. In all cases in which we can determine that the progress of the disease has been arrested, will our prognosis be the more favourable; but in those in which the secondary symptoms which we have several times brought under the notice of the reader, are present, the death of the patient may be regarded as inevitable.

Treatment of Mortification.—The treatment of mortification from inflammation must be conducted in reference, 1st, to the cause of the disease; 2d, to the disease itself; and, 3d, to its effects, mediate or immediate. With regard to the first head, the efficacy of the means employed will depend much on the extent and degree of the inflammation which accompanies the stage of gangrene or sphacelus, the nature of the affected organ, and the general condition and age of the patient. The progress of the inflammation may be arrested, or its violence moderated, by the prompt and well-regulated use of antiphlogistic remedies, such as general and local bloodletting, saline purgatives, rest, quiet, and total abstinence from food. In those cases in which the inflammatory symptoms have been slight, even from the commencement of the disease, the antiphlogistic treatment has been found to be injurious rather than beneficial, both on account of the debility which is present, and because of its having appeared to retard or prevent the accomplishment of that salutary process by means of which the progress of the disease is arrested. There are other cases in which the use of antiphlogistic remedies is forbidden, by the nature both of the general and local symptoms. There is a total absence of pain, no sign of inflammation in the affected organ, and a state of general debility or prostration. The early occurrence of these symptoms, as well as their presence in the last stage of almost every case of mortification, have rendered many physicians very cautious in the use of debilitating remedies, and have induced them to place more reliance on the judicious employment of tonics and stimuli, and other means calculated to support the strength of the patient, and assist nature in carrying on the process of elimination and reparation. It is only by a knowledge of the circumstances of each case that we can at all judge of the applicability of either mode of treatment, or when the one should be employed in preference to the other. It is on the same principles that we can reasonably hope to exercise a salutary influence over the disease itself, that is, as regards the removal of the dead portion, and preventing the effects to which it gives rise. The most dangerous of all the effects of mortification are those which follow the absorption of the putrid fluids of the sphacelated tissues, to remove or even mitigate which no means have yet been devised on which any reliance can be placed. It has been proposed to employ solutions of the chlorides of lime and soda, as washes, to destroy the putrid effluvia which accompany sphacelus. We are not certain how far they have been found to accomplish the end in view. Besides, these solutions can be had recourse to only in a very limited number of cases of this disease, and when confined to the organs of generation and the urinary bladder.

II. Mortification from a mechanical obstacle to the circulation of the blood.—The blood may be prevented from arriving at, or returning from, a part of the body by mere mechanical causes. In both cases mortification is the consequence of the cessation of the function of nutrition, either from a deficiency of the arterial or the stagnation of the venous blood. A deficiency of the arterial blood may be occasioned by ligature of the principal artery of a limb, a collateral circulation sufficient for the nutrition of the limb not having been formed; or it may follow in consequence of coagulated blood, or fibrine, organized or unorganized, occupying the entire calibre of such an artery or its principal branches, from ossification of the walls of these vessels, or their conversion into a solid fibrous or ligamentous tissue.

Stagnation of the venous blood may depend on obliteration of the veins caused by the pressure of tumours situated in their immediate vicinity; accidental products formed in their cellular sheath; or the presence of fibrine or other solid substances derived therefrom, formed within the veins, and either simply lodged within them, or more or less intimately connected with their lining membrane; and, lastly, diseases of the heart, which greatly obstruct or prevent the return of the venous blood to this organ. Mortification may also occur in consequence of the arteries, veins, and nerves having all at the same time been submitted to severe pressure, as in the case of ligature and tumours.

Mortification from a mechanical obstacle to the circulation of the blood is by no means equally frequent, either as regards the causes we have just named, or the part of the body in which it occurs. Mortification in consequence of the stagnation of the venous blood is much more often seen than that which follows an obstacle to the arterial circulation, owing obviously to a difference in the organization and relations of the arterial and venous systems, whereby the latter is more frequently and more easily subjected to the influence of mechanical agents, capable of modifying, in the manner alluded to, the circulation of the blood. Mechanical causes which compress or obliterate the veins are often incapable of producing the same effects on the arteries, from the circulation in the former tending to favour rather than oppose their operation, and which in the latter has a powerful influence in resisting every external force which tends to diminish their capacity. And besides, stagnation of the blood in the venous system, by whatever cause produced, may, correctly speaking, be said to depend on the relation which exists between it and the arterial system; that is to say, the mechanical cause is but an obstacle to the passage of the venous blood, while the quantity of this fluid and the extent of the stagnation that follows are determined by the arterial system.

The situation of parts and the mode in which their circulation is affected, are circumstances which modify in a remarkable manner the fre-

quency of mortification. Mortification from mechanical causes which obstruct the circulation of the blood, occurs in the great majority of cases in the extremities, and far more frequently in the inferior than in the superior, partly from their being isolated from other organs which might facilitate the formation of a collateral circulation, and partly from their situation and position, both of which are unfavourable to the circulation of the blood. Mechanical causes, which produce general death when situated in organs on the integrity of whose functions life in general more or less immediately depends, give rise in them only to local death or mortification. In the former the operation of these causes is necessarily of short duration, and is always confined within narrow limits when it is carried to a degree to produce *sphacelus*. Should their influence extend to the circulation of the whole of an organ, such as the lungs or liver, the obstacle to the return of the blood from either being situated in the heart, a state of general congestion is produced, but which never amounts to what is properly called gangrene.

In the latter, on the contrary, mechanical causes which impede or interrupt the circulation of the arterial and venous blood, may continue to operate for a considerable length of time, producing all the regular stages of mortification, as various degrees of congestion, gangrene, and sphacelus. Mortification, however, does occur in the extremities without being preceded by these changes, the reason of which we shall endeavour to assign presently.

With regard to the relative frequency of mortification of the kind of which we are now treating, it is also of importance to know that this disease is more frequently produced by disease of the heart than of the blood-vessels, and that in this case it is never observed in any other part of the body than the inferior extremities. There are, however, several circumstances, to which we shall particularly allude hereafter, which hasten the termination of congestion of these parts from disease of the heart, in gangrene and sphacelus, and without which such a termination would not unfrequently not take place.

From these general remarks on the influence of mechanical causes, operating through the medium of the circulation, in the production of mortification, and the comparative frequency of this disease in different parts of the body, it is obvious that the descriptive characters of this disease so produced must be founded on the phenomena which it presents when it affects external organs. We shall therefore commence with the description of that form of the disease which occurs most frequently, and which affects the inferior extremities in consequence of an obstacle to the return of the venous blood from these parts, produced by disease of the heart.

1. Mortification of the inferior extremities from disease of the heart. — The first local sign that an obstacle exists to the return of the venous blood from the inferior extremities is manifested by the appearance of slight œdema around the ankles. The serosity gradually accumulates in those parts, spreading thence throughout the cellular tissue beneath the skin and between the muscles; the feet, and afterwards the legs, thighs, and scrotum in the male, and labia pudendi in the female, become swollen; the skin assumes a smooth and glossy aspect, feels tense, and sinks into the cellular tissue when pressed, and does not resume its former shape and situation till raised by the return of the serosity beneath it. The colour of the skin, at first natural, becomes pale and waxy, and may continue in this state during the greater part of the course of the disease. When discoloration of the skin is about to take place, it is seen to depend on the presence of a few subcutaneous veins, which gradually increase in bulk and number, coalesce in several points, and communicate a slightly mottled aspect to the skin, of a dull red or purple colour. On one or more of these points where the congestion is greatest, and where the skin is less yielding, as over the tibia and above the malleoli, phlyctenæ or large bullæ are formed by the effusion of serosity, either alone or mixed with blood, under the cuticle. When these burst, the cutis beneath presents a dark red or brown colour, and very soon is converted into a dirty yellow or ash-grey slough. The separation of the slough is sometimes preceded by an increase of redness in the surrounding cutis, which, from its anatomical characters and the increased temperature and pain by which it is accompanied, is obviously of an inflammatory nature. At other times the redness which precedes or accompanies the separation of the dead part is very slight, and is evidently owing to mere venous congestion, occasioned not only by the disease of the heart, but also by the serosity accumulated in the cellular tissue of the limb, which, from the pressure it occasions, further retards the return of the venous blood, and aggravates all the symptoms produced by the primary cause of the disease.

Although, after the separation of the slough, a loss of substance of considerable extent in depth may appear to have been produced, it perhaps never proceeds beyond the cellular tissue; and it is because of this tissue being greatly distended with serosity, that the loss of substance which follows sloughing appears to have penetrated deeply into the substance of the limb.

Congestion, gangrene, and sphacelus may take place on several parts of the leg, but they are in general limited to the parts we have enumerated, and rarely occur on the feet or toes.

We have already remarked that the temperature of the extremities is always below the natural standard during the first periods of the disease, and that it does not acquire a morbid increase till the distension of the cutis is great, and this tissue becomes discoloured from the congested state of the capillaries. An increase of the sensibility takes place at the same time, and is always greatest where the cutis is most distended, and sometimes amounts to a degree of pain of a darting, pungent, or burning character, which greatly increases the sufferings of the patient. Although the temperature and sensibility of the limb are sometimes very great while the cutis is still entire, but tense, congested, or inflamed, they are never so considerable as when sloughing has taken place, accompanied by inflammation of this tissue. It is also in such cases that the pulse becomes

quick and the skin in general hot;—in one word, that febrile symptoms make their appearance. Under these circumstances life is seldom prolonged beyond a few days, otherwise the death of the whole limb would follow as the inevitable consequence of the increased disturbance of the circulation, occasioned by the febrile excitement;—a termination which the author of this paper has witnessed in two cases, in one of which the sphacelus extended even to the walls of the abdomen.

The progress of this kind of mortification, although generally slow, is occasionally very rapid. This difference depends chiefly on the two following circumstances,—a naturally unyielding state of the skin, and the effect produced on the venous circulation of the limb by the effused serosity. It is principally to the latter circumstance that we wish to direct attention, as it may suggest some means to prevent its occurrence and the evils by which it is followed. As soon as the blood has accumulated to a certain extent in the venous system of the inferior extremities, serosity is effused in greater or less quantity, and compresses the veins. A second obstacle is thus created to the return of the venous blood, and consequently the progress and termination of the disease are greatly accelerated. These effects of compression from the effused serosity are first manifested by the sudden appearance of congestion of the skin, which generally occupies the greater part of the leg. The skin retains its glossy aspect, but becomes all over mottled with various shades of red and purple; is seen traversed in every direction by minute veins and capillaries distended with blood, and the whole limb acquires a degree of hardness peculiar to this state of the circulation. The sloughing which follows may take place without the supervention of inflammation,—at least without this state being marked by uniform redness of the skin,—is more extensive than in the previous form of mortification, but does not extend beyond the skin and cellular tissue.

The separation of the sloughs in mortification from disease of the heart is seldom followed by hemorrhage; and when it does occur, it consists merely in a slight oozing of blood from one or more points of the denuded surface. This circumstance, as well as the state of the blood generally found in the veins after death, is readily accounted for. The blood in the veins in the immediate vicinity of the sphacelated part of the limb, is found coagulated, or these vessels are filled with fibrine. More remote from this part, and sometimes in the greater part of the limb, the blood with which they are distended is also more or less coagulated, but becomes more fluid as we examine it further from the seat of the sphacelus.

Prognosis.—In no disease can our prognosis be more certainly fatal than in mortification in consequence of disease of the heart. Its very occurrence is a sure evidence that the disease on which it depends would soon terminate fatally without the aggravation of suffering which this, perhaps the worst of its effects, never fails to produce. The only favourable circumstance—if such it can be called—relates to the duration of the disease. If the mortification is the consequence of the stagnation of the blood occasioned by the disease of the heart alone, we may venture to predict that its progress towards a fatal termination will be slower than when to this, the primary cause, is added the obstructing influence of the effused serosity.

Treatment.—The treatment of mortification from disease of the heart is not only extremely restricted but entirely palliative. The general treatment which has been or is still employed against the primary disease, and which has been found ineffectual in arresting its progress, is also that which, if no such disease existed, would be adopted for the cure of the mortification. Under such circumstances experience has shown that little more can be done for the patient than to mitigate his sufferings by the frequent administration of anodynes; the application of cold lotions, warm fomentations or poultices to the affected limb; using one or other of these as the feelings of the patient or the stage of the disease may suggest. Both on account of the patient and the assistants, a solution of the chlorides should be used so soon as sloughing has taken place. The limb should also be kept in an elevated position by means of pillows; and as the foot is often cold while the leg is painfully hot, some relief is obtained by covering the former with warm flannel, and the latter with compresses that have been dipped in cold water or the saturnine lotion. It is probable that the occurrence of mortification from disease of the heart might in some cases be prevented by the early confinement of the patient to the horizontal position, by the occasional use of friction with a view to facilitate the venous circulation of the extremities, and the application of a well-adjusted bandage from the toes upwards, which would not only prevent the occurrence of great congestion by equalizing the circulation throughout the limb, but also the œdema which follows, and so greatly aggravates the disease.

2. Mortification of internal organs from a mechanical obstacle to the return of the venous blood.—We do not believe that there is a single example of mortification of an entire internal organ from an obstacle to the return of the venous blood, and produced by a mechanical cause. We have already stated the reason of this exception, namely, the facilities afforded for the formation of a collateral venous circulation; and the duration of the mechanical cause capable of producing local death being limited by the greater importance of these organs. Mortification of portions of internal organs is, however, occasionally met with, and which can easily be traced to cessation of the circulation from compression of the veins: the lungs, liver, and intestines are the organs in which this form of mortification is most conspicuous. It occurs in the lungs when the cellular structure of these organs has become consolidated by the deposition of coagulable lymph, and produces that state of the pulmonary tissue termed *hepatization*. We allude here to the *grey* hepatization most frequently observed around tubercular excavations, and which is regarded as the consequence of chronic pneumonia. The colour of the indurated pulmonary substance may be grey, purple, livid, or nearly black, and its consistence sometimes such as to equal that of cartilage. In this state it is highly probable that

it never regains its natural structure and consistence. When carefully dissected, not only are the veins contained within it found compressed or obliterated, but also the arteries are much diminished in bulk. In fact, all the elementary tissues of the indurated portion of lung are atrophiated; and if the accidental deposit by which these changes are produced is not removed by absorption, the former are soon deprived of their vitality, and both are converted into a soft substance, the colour of which will depend on that of the part previous to this change, as well as the degree of putrefaction which it may have undergone before it can be examined.

Sphacelus of the walls of tubercular excavations is sometimes produced in a similar manner. The veins and arteries which traverse the septa, or ramify in the walls of these excavations, become obliterated by the conversion of the blood which they contain into masses of firm fibrine. This change may take place previously or subsequently to the formation of the excavations. In the former case the expectoration is copious, sometimes contains pretty large portions of tuberculous matter and softened cellular substance, the odour of which is extremely offensive. In the latter case the only change observed in the expectoration is a tinge of brown, dirty grey, or green, with perhaps a more marked odour of sphacelus.

Induration of the pulmonary tissue and compression of the veins may likewise be produced by the tuberculous matter, when deposited in such quantity as to occupy a large portion or the whole of the lobe of the lung. The author of this article has represented a striking example of induration from infiltration, as it is called, of tuberculous matter terminating in sphacelus, in the first Fasciculus of his work on the "Elementary Forms of Disease." The whole of the upper lobe of the right lung was converted into a solid mass as firm as a piece of boiled cow's-udder, of a pale straw colour, of a homogeneous aspect, and presenting here and there only a few faint traces of the interlobular sections. The upper portion of this lobe contrasted strongly with what we have just described. It was converted into a mass of dirty yellowish grey substance as large as an orange, some parts of it soft and spongy, others quite pulpy or consisting of a dirty grey sanies, in which the blood-vessels, veins, and arteries, were lying denuded and obliterated by firm coagula. There was no increase of vascularity, indicative of previous inflammation, in the infiltrated pulmonary substance, around this the sphacelated portion; and therefore we regard this case as strikingly illustrative of the manner in which local death is not unfrequently produced by the accumulation of accidental products of the parenchyma of organs.

When speaking of mortification of the lungs from inflammation, we alluded to the occasional occurrence of this disease without it, being preceded by the usual phenomena of pneumonia. Although we are not prepared to demonstrate that such cases should be considered as of the same nature as those we have included under the present head, we are satisfied that we have seen one or two instances of sphacelus of the pulmonary tissue depending on induration as a consequence of chronic pneumonia. This opinion is founded not only on the sudden occurrence of the state of sphacelus without the signs or symptoms of previous inflammation, but on the presence of grey indurated pulmonary tissue, which we found forming part of the boundary of that which was sphacelated: such a degree of induration could not have been produced by adhesive inflammation, subsequent to the sphacelus, as death took place within too short a space of time to allow of such being accomplished.

Sphacelus of portions of the liver is not very rare in those cases in which it is nearly filled with cancerous tumours. These tumours produce, mechanically, extensive obliteration of the veins; and when a portion of the liver becomes incarcerated by them, it is converted into a dark brown slough, generally soaked with blood, and sometimes mixed with softened and detached portions of the neighbouring tumours.

An obstacle to the venous circulation gives rise more frequently to sphacelus in the digestive organs than in the liver. It is chiefly in the intestines that cessation of the circulation from a mechanical cause is seen to terminate in sphacelus: we shall adduce one example only of sphacelus, namely, that which occurs in the intestines in the case of intus-susception.

We shall allude shortly to the mechanism of this morbid condition of the intestine, in order that the cause of the sphacelus, in which it sometimes terminates, may be clearly understood. When the superior portion of intestine passes into the inferior, or becomes invaginated, it carries along with it that part of the mesentery to which it is attached. If it does not suffer much compression, the invaginating process may go on to a great extent; but if it is compressed to such a degree that the return of the venous blood is obstructed, this stage of the disease is arrested, on account of the congestion which follows of all the coats of the invaginated portion. The congestion is not the consequence of inflammation; it is produced by pressure, and in the following manner: when the mesentery is put on the stretch by the descent of the superior into the inferior portion of the intestine, the veins belonging to it are compressed between the walls of both portions, just at the point where the invagination terminates superiorly. If adhesive inflammation takes place at this point, the peritoneal surfaces of both portions become united, and the veins obliterated. As the arteries are much less affected by pressure than the veins, they continue to pour their blood into the invaginated portion; this fluid gradually accumulates, and produces an extreme degree of congestion of the mucous and submucous coats, giving to them a deep red or almost black colour. In this state, however, the intestine is not deprived of its vitality. It is in a state of gangrene, but not of sphacelus; for its structure is still entire, and when it has been separated and evacuated, presents, after having been macerated for some time, so as to deprive it of the blood which it contains, the most perfect state of integrity of all its tunics. Occasionally, however, a portion or the whole of the invaginated intestine is found in a state of com-

plete sphacelus, and is passed in the form of irregular spongy masses or shreds of a dirty ash-grey, brown, or black colour.

It is not unimportant to know that the invaginated intestine may be detached in separate portions, and passed at different intervals of time. In such a case the physician might be led to suppose that there were several distinct portions of intestine invaginated, whereas there is only one portion. If the invaginated portion of intestine be considerable, it is, perhaps, never separated all at once; on the contrary, it is detached, as we have said, in several distinct portions, two, three, five, or even eight; differences which depend on the manner in which the invaginated intestine is disposed of. For if considerable, it does not present a cylindrical form; it is drawn up into the form of abrupt, flattened, or angular coils, determined by the attachment of the vessels and mesentery, so that stagnation of the blood takes place successively in different points, and from below upwards, being always greatest at the inferior extremity of the invaginated portion.

The symptoms of intus-susception derive no peculiarity from the existence of gangrene or sphacelus, unless when a part or the whole of the invaginated portion is passed by stool. We may, however, observe that this disease may, in the great majority of cases, be distinguished from stricture of the intestines occurring after ulceration, by a careful examination of the previous history of the patient. Disorder of the functions of the digestive organs, referable to chronic disease of the intestinal canal, will be found to have existed for a greater or less length of time before the occurrence of those symptoms which indicate an obstacle to the passage of the food or fæces from stricture: these symptoms are but slight at first, repeated at irregular intervals of time, and become more aggravated at every succeeding attack; whereas in intus-susception the presence of a mechanical obstacle is announced suddenly without being necessarily preceded by any marked derangement of the functions of the intestine; the symptoms to which it gives rise are rapid in their course, steady in the increase of their severity, and are aggravated by all the internal remedies calculated to relieve or remove the former.

There are no means of distinguishing this disease from internal strangulation of the intestine until the sphacelated portion is passed by stool. The existence of the former disease may, perhaps, be suspected previous to this period by the oozing of blood from the congested mucous membrane of the invaginated intestine.

The natural cure of intus-susception furnishes us with the most interesting examples of the efficient good which can be accomplished by adhesive inflammation. The serous membranes being endowed with a property which enables them to supply a quantity of coagulable lymph sufficient for the full accomplishment of this process, by the lowest possible degree of inflammation, the solution of continuity which follows the separation of the dead portion of the intestine is often repaired without any appreciable disturbance of the economy. The union of the intestine, let it be remarked, is effected, not between a mucous and serous surface, but between the *two serous surfaces* of the invaginated and invaginating portions of the intestine, and just at the point where the invagination commences: there the separation takes place, and there also the union is effected previous to the separation, which is to maintain the continuity of the intestine, and secure the life of the patient. Under these circumstances the diameter of the intestine may not undergo any perceptible change, and the passage of the food or fæces is accomplished with the same facility as before the occurrence of the disease.

It is consolatory to know that patients may survive the loss of a considerable extent of intestine from intus-susception, and that, too, without their general health having suffered any perceptible alteration. By far the most remarkable instance of this kind that has come to the knowledge of the writer of the present article, occurred in the practice of his excellent and distinguished friend, Dr. Forbes, of Chichester, with whom he had the opportunity of examining several of the portions of intestine passed by the patient. There was no less than *eight* portions of intestine passed by stool, varying from eleven to thirty-two inches in length, the length of the whole amounting to *twelve feet of entire intestine!* Each portion was complete in itself, presenting, in fact, the appearance of healthy intestine, that has been allowed to remain for a certain length of time in alcohol. They consisted of the jejunum and ileum, some of them having their serous, others their mucous surface outwards (which is always the case when the intus-suscepted intestine separates in distinct portions), on the former of which the blood-vessels, on the latter the glandulæ agminatæ, were most conspicuously visible. The most interesting feature of this case was the complete recovery of the patient, at least from the immediate consequence of this disease. The subject of this remarkable case was a poor woman of the name of Ann Newland, resident at Emsworth, in Hampshire, and was a patient of Mr. Lyne, surgeon at that place. She had been confined to bed by an anomalous chronic affection for many years previously to the intus-susception. The first portion of intestine came away in the year 1826, the last in 1829. She died in March, 1831, aged thirty-seven years. The greater part of the intestine passed, is preserved in the Museum of the Chichester Infirmary.

This case also acquires great additional value from the circumstance that the form and dimensions of the intestine, at the point where the solution of continuity had taken place, were found, after the death of the patient, to have undergone very little alteration. A slight contraction of the small intestine, and the presence of a thin, pearly-coloured false membrane, little more than half an inch in breadth, and surrounding it in the form of a zone, were the only external appearances which indicated the original seat of the disease. On the corresponding and internal surfaces of the intestine there was also seen a narrow, slightly elevated, smooth ridge, covered by mucous tissue, and traversing the whole circumference of the intestine, the walls of which, opposite, were considerably thickened.

If any doubt could remain that these appearances were to be admitted as positive evidence of

the union and cicatrization of the original solution of continuity of the intestine, that doubt would be entirely removed by the fact that the solution of continuity had taken place in the situation of one of the glands of Peyer, and in such a manner that this gland was divided into two nearly equal portions, one of them terminating in the cicatrix, and the other being situated at the extremity of one of the detached portions of intestine.

With regard to the treatment of mortification from intus-susception, there are two points which deserve the chief consideration of the physician; the reduction of the invagination, and the separation of the dead portion of intestine. The reduction of the invagination is not to be effected by the *direct* operation of any means which we have in our power to employ. If this is at all to be accomplished, it must be by preventing the accumulation, or diminishing as much as possible the quantity of the fluid contents of the intestine, —that is to say, by confining the patient to a state of absolute rest, by depriving him of food and drink as long as possible, by general blood-letting, and the use of emetics so employed as not to act upon the intestine. Purgatives must be avoided, as having the direct effect of increasing the disease. If this treatment fails to give relief, the physician should act as if there were a certainty that the reduction of the invagination is rendered impossible by the adhesive inflammation, and that a cure may be expected to follow the separation of the dead part of the intestine. Under these circumstances he must wait patiently, and endeavour to remove every cause which can tend to retard or prevent the accomplishment of this salutary result. At this period of the disease he cannot do better than enjoin rest and quiet, and support the strength of the patient by the frequent administration of small quantities of nutritious fluids, or enemata of a similar kind.

Numerous examples of mortification from an obstacle to the venous circulation are met with in those adventitious formations known under the denominations of scirrhus, cancer, medullary sarcoma, fungus hematodes, fibrous tumours, &c. We do not, however, think it necessary to do more than indicate the occurrence of the disease in such cases, as we have already alluded to it when speaking of mortification of the lungs and liver produced by a mechanical obstacle to the return of the venous blood. Such adventitious products, from their situation, connection, and mode of development, are often destroyed in part, and sometimes entirely, solely on account of the veins in their immediate neighbourhood, or contained within them, being so compressed as to prevent the passage of the blood through them. These substances become gorged with blood, particularly at their circumference, where sloughing commences, which proceeds towards their interior, with a rapidity and extent proportioned to the degree of congestion by which it is preceded.

The rapid development of some of these accidental formations often depends on the destruction of the surrounding tissues by mortification, whereby they are relieved from the restraint imposed on them by external pressure. They now shoot forth with surprising rapidity, and undergo such a change in their conformation and other physical characters, that, although still the same disease, they are no longer recognised as such, and receive new names, which not a little embarrass the student of pathology.

3. **Mortification from obliteration of the Arteries.**—Although this form of mortification, confined as it is almost always to the extremities, be regarded as the exclusive object of surgical treatment, we shall give a small outline of the pathology as it occurs in two distinct morbid states of the arteries of these parts, that the physician may be the better prepared to distinguish it from that which arises from disease of the heart, and another form of mortification of the extremities which still remains for us to describe,—viz. that occasioned by the use of unsound rye as an article of food.

The two forms of mortification of the extremities to which we here allude, originate, the one in spontaneous rupture of the internal and middle coats of the trunk of an artery, the other in the obliteration of a similar vessel or of its principal branches by the presence of organized fibrine, fibrous or osseous substances.

Mr. J. W. Turner, professor of surgery in the University of Edinburgh, was the first who directed the attention of the pathologist to the occurrence of spontaneous rupture of the internal and middle coats of an artery. There is, however, nothing in the histories of the cases which he has published which throws any light on the morbid condition of the arteries which precedes the rupture of their internal and middle coats. That such must have been the case is obvious from the following facts. One of the patients, whose case is related by Professor Turner, was in the act of raising himself in bed by resting on the palms of his hands, when he experienced a sensation as if something had given way at the joint of the right arm. Five days afterwards, the same patient, while in the act of moving his right leg, perceived a sudden sensation of numbness and weight extending from the ham downwards. Another patient, while turning his hand behind his back to put in his coat-pocket, felt a sudden acute pain in the bend of the elbow joint, and a sensation of numbness in the hand and fore-arm. It is, therefore, obvious that in none of these cases the rupture, which was afterwards found to have taken place in the internal and middle coats of the brachial and popliteal arteries, could have been produced had there not existed a previous state of disease of these vessels. In one of the cases only did mortification take place. Half an hour after the rupture of the popliteal artery, no pulsation could be felt in any of the arteries of the foot, or in the ham. The foot was cold: no pain was excited by pressure on any part of the limb, but the patient complained of occasional cramp-like pains in the calf of the leg. The morning after the attack the foot was pale and cold, and below the ankle the integuments were entirely void of sensation when pressed, pinched, or tickled, and the muscles of the foot seemed to have lost the power of contraction. The next day several mottled purple patches appeared on the instep and fore-part of the ankle, which gradually extended over the whole foot, till the surface, by the fifth day, became entirely livid. As the discoloration

advanced, the foot swelled slightly, and became œdematous, and appeared to acquire an increase of temperature. Soon after the attack the patient complained of severe burning pain in the foot, and a feeling as if it were crushed, which continued till near his death. About the ninth day the soft parts above the ankle began to swell and to be hot and painful on pressure; the swelling gradually increased, and extended till it reached the upper part of the calf of the leg. The integuments above the ankle began to become discoloured at the same time, and the discoloration increased till the lividity reached the calf of the leg, and at last rapidly extended nearly to the knee. The soft parts adjoining the discoloured skin were swollen and very painful on pressure; but no redness appeared, nor any inflammatory line between the dead and living parts. The parts discoloured were completely sensible, and the cuticle raised into globular vesications, filled with limpid or reddish serosity. The constitutional symptoms in this case were greatly aggravated by a previous state of disease. Death, however, did not take place till eighteen days after the pulse had ceased in the leg. The coats of the artery were found torn, thickened, and obliterated in several points by coagulated blood, fibrine, and lymph.*

The second form of obliteration of the arteries which gives rise to mortification, consists, as we have said, in the presence of fibrine, fibrous, or bony substances formed in these vessels. When the quantity of these substances is such as to interrupt or prevent entirely the circulation of the blood through the principal arterial trunk or branches of one of the inferior extremities, mortification is almost always the consequence, because of the advanced period of life at which this form of the disease generally occurs, and the very unfavourable state of the arteries to the formation of a collateral circulation.

It is to this form of mortification that we would confine the term **gangræna senilis**; the *idiopathic* and *dry* gangrene of authors.

We have already stated one of the reasons which have induced us to give a general outline of the kind of mortification which we are now describing, and we might have added a still more weighty reason for our doing so; viz., the important pathological evidence with which it furnishes us in regard to the production of mortification, independently of the previous existence of local inflammation; a subject on which it would appear some doubt is still entertained. We should not have thought it necessary to recur to this circumstance, having already shown that mortification, from a mechanical obstacle to the return of the venous blood, and produced in a variety of ways, is not an uncommon occurrence in internal organs, were it not that the facts then adduced might be regarded as incomplete, from their being chiefly founded on the results of post-mortem examinations. In the form of mortification which we are now about to describe, no such objection can be raised, as all the facts which the pathology of a disease can afford as evidence of its seat and nature, are, in this case, equally conspicuous and decisive.

The first change which announces the occurrence of local death from obliteration of the arteries of one of the inferior extremities, occasioned by the presence of the accidental products which we have named, is a dark-red, purple, or almost black discoloration of the skin of the fleshy or under portion of one or more of the toes of the foot. There is, in general, no previous swelling of the affected toes, no increase of their temperature or sensibility. The discoloration, alone, is often the first circumstance which attracts the attention of the patient to the existence of the disease; and we have seen two cases in which the discoloration had gained the upper surface of the toes, before the patients were aware of the presence of this insidious and fatal affection. In some cases, however, a prickling or tingling sensation, or a certain degree of numbness and cold, are perceived in one or more of the toes, and which, when examined, are already found to be discoloured; not red, hot, swollen, and painful, but of a purple or livid colour, colder than natural, not painful when pressed, and shrunk rather than increased in bulk. An increase of temperature, sensibility, and bulk of the affected toes, is, however, occasionally observed at or near the commencement of the disease; but as they are not constant, so are they not necessary changes. This, the first period of the disease, presents, indeed, none of the local characters of inflammation, if we except the circumscribed accumulation of blood on which the discoloration of the skin of the toes depends, the isolated existence of which is, however, of no value, inasmuch as its presence can be accounted for from interruption to the arterial circulation of the limb.

The discoloration extends slowly until it has pervaded the whole of the skin covering the toes, then proceeds upwards over the back and sides of the foot, and sometimes mounts nearly as far as the knee, although more frequently death takes place from the constitutional disturbance which ensues, before it has passed the foot or ankle joint. During its progress, the discoloration generally presents the same purple or livid tint which it did at the commencement; and although it may be preceded by some swelling and congestion of the skin and subcellular tissue, its progress is seldom marked by the bright red colour of inflammation; and when inflammatory redness of the skin takes place, accompanied with heat, pain, and tumefaction, these phenomena must be regarded as effects of the disease which more frequently tend to increase than to interrupt or arrest its progress.

The bulk of the affected parts depends chiefly on the situation and extent of the obstacle to the circulation. If the obstacle be extensive, the quantity of blood admitted to the foot is too small to give rise to congestion; and this not taking place, there is little or no effusion of serosity. Hence there is no increase of bulk in mortification from this cause; and if the obstruction has been effected slowly, the foot and leg may even be atrophiated previously to their being attacked with mortification, the dead parts being shrunk,

* On the sudden spontaneous Obliteration of the Canals of the larger Arteries of the Body, &c. by J. W. Turner, Professor of Surgery in the Royal College of Surgeons, Edinburgh. Edinburgh Medico-Chirurg. Society's Transactions, vol. iii.

dry, and indurated. These physical characters of the disease are entirely owing to the hydraulic conditions to which we have just alluded; for if the obstruction to the passage of the arterial blood be only partial, and particularly if it has occurred suddenly, a considerable degree of congestion is induced, and consequently the effusion of a greater or less quantity of serosity, whereby the bulk of the foot, and more frequently of the leg, is more or less increased: even in this case, however, there is not any marked increase of bulk in the toes, the primary seat of the disease. It is in its progress upwards that the congestion and œdema become manifest; that the skin becomes tense and painful; and that the febrile symptoms, if they have not yet occurred, appear, increase rapidly in severity, aggravate the local affection, and hasten its fatal termination.

From the nature of the obstructing cause, and the unfavourable conditions under which it occurs, the progress of the mortification is seldom arrested; and if it is so, the separation of the dead parts is rarely accomplished, and perhaps a cure never effected.

It is stated by some pathologists that this form of mortification sometimes occurs in young persons, and is much more frequently met with in males than in females. The former statement we believe to be an error originating in an imperfect knowledge of the causes of this disease; for as we ourselves have never seen it in young persons, and as this statement has not been supported by other than mere negative facts, and these too very incomplete, we must continue to regard it as a disease peculiar to persons advanced in life, and occasioned by morbid states of the arterial system, which occur only in such persons, at least to such an extent as to produce local death.

With regard to the greater frequency of the disease in males than in females, we should say from our own personal observation, that this statement is correct only in so far as it regards its occurrence in the inhabitants of towns and cities; but that in those of agricultural districts, where the occupations and mode of living of both sexes are much of the same kind, it appears to occur as often in females as in males.

In every case of gangrena senilis which we have examined after death, we have found the arteries of the diseased limb obliterated in such a degree as to interrupt the circulation of the blood. The obstructing cause consisted, in five or six cases, of a fibrous tissue formed either in the walls or cavities of the arteries, whereby these vessels were converted into nearly solid cords of ligamentous consistence. This state we have traced from the toes more than half way up the leg; it was always connected with ossification of the larger branches and trunks of the thigh and other parts of the body. In other two cases, the obstruction depended on extensive ossification of the principal arteries of the limb; and in several others it was produced by solid fibrine formed around spiculi of bone projecting from the internal surface of the arteries.

Connecting this state of the arteries with the external appearances of the mortification with which it is accompanied, we can have no hesitation in admitting that this form of the disease is the immediate consequence of a deficient supply of arterial blood, and that therefore, if the facts already adduced were considered insufficient to prove that some of the other forms of mortification which we have described may also take place without being preceded by inflammation, those which we have now brought forward will, we trust, remove any doubts that may have been entertained on this highly important part of our subject.

The description which we have given of these two forms of mortification from rupture of the internal and middle coats of the arteries, as well as from obliteration of these vessels, is, we hope, sufficiently characteristic, and such as will enable the physician to distinguish them from other forms of this disease which belong especially to his department of the healing art.

III. Mortification from local and general debility.—As a state of local debility capable of inducing mortification is always connected with, and essentially depends on, a state of general debility, we shall confine the observations which we have to make on this form of mortification to the affection as it occurs under the influence of the latter condition of the economy.

Whatever may have been the causes of the general debility, we regard this state as constituting the essential condition of the disease;—a state in which the physiological and physical properties of the solids and fluids of the body are so modified, (we commonly say enfeebled or debilitated,) that every function of the economy is slowly, ineffectually, or imperfectly performed: innervation and nutrition in particular are so circumstanced, that even those agents on which the varied phenomena of health and life more or less immediately depend, now become the causes of disease and of death. Illustrations of this important fact meet the eye of the physician in the every-day occurrence of diseases of various kinds, but they seldom arrest his attention unless they occur under extraordinary circumstances,—such, in fact, as are observed in those cases of decay and death of the solids to which we shall presently more particularly allude. We have seen that mortification of various parts of the body may be produced by mechanical causes whose operation is entirely limited to the vascular system, in which they impede or arrest the circulation of the blood. This fluid, as well as the solids in general, may be in the healthy state up to the moment at which the local mechanical cause begins to operate and manifest its effects, and these are characterized by a diminution of all those properties, the extinction of which is the death or mortification of the part thus circumstanced. A similar healthy condition of the solids and fluids may precede mortification from inflammation, but the phenomena of the disease are the opposite of the former. Local death does not take place until after the morbid stimulus has increased every property of the part to which it has been applied, to its maximum. The part is thus exhausted of its strength, if one may be allowed the expression, and being deprived also of the means of renewing it, from the changes which have taken place in its more essential elements, it soon sinks into a state of absolute death. In the form of mortification of which we have

now to speak, the fluids of nutrition as well as the solids are, as we have said, in a previous state of disease, and this state is the cause of the general debility which constitutes the essential character of this form of mortification. Notwithstanding, we have classed it with the two former, because of their being all preceded by the same state of the circulation. In none of these three forms of mortification does local death take place without being preceded by cessation of the circulation; a circumstance, we believe, of sufficient importance to authorize our having brought them all under the same general head.

The most marked examples of mortification from general debility are met with in individuals whose strength is greatly reduced by want and fatigue, by the violence of acute diseases of an adynamic character, and by chronic diseases accompanied with much pain, extensive suppuration, or which compel the patient to remain for a long time in the same position. Under these circumstances the local phenomena of mortification present, no doubt, considerable variety; but those which constitute the type of the disease, whether local or general, are always the same, unless in so far as they vary in extent and degree. Thus, mortification from debility may be preceded by a certain degree of pain, increased sensibility and temperature of the part affected; but these changes are not constant, and therefore not necessary to the production of the disease. A local accumulation of blood constitutes, in general, the first perceptible change in the part which is about to be deprived of its vitality. This may take place from the part being submitted to pressure from its own weight or that of the body, from slight friction, puncture, or similar causes. In some of these cases the blood accumulates, partly from the influence of gravitation, and partly from compression of the veins; as, for example, in mortification of the soft parts covering the sacrum, heels, elbows, &c. of persons who have escaped the dangers of typhoid fevers, and who are left in that state of prostration which precludes the possibility of changing the position of the body. It is, perhaps, still more conspicuous in some patients similarly confined with paraplegia from injury of the spinal cord. Sloughing, or at least sphacelus, may have proceeded to a considerable extent before its existence has even been suspected; the patient seldom complaining of any uneasiness till inflammation has been induced by the presence of the dead tissues.

A state of local congestion is also frequently the only change which precedes the sphacelus of the skin to which leeches have been applied, or which has been scarified or punctured. The skin around the leech-bites assumes a dirty purple, livid, or almost black colour; looks sometimes as if it had been injected with ink; presents no previous redness, heat, or pain, and is not swollen except where the blood is accumulated; it drops off in the course sometimes of twenty-four hours, leaving a number of circular openings, which unite and spread by similar succeeding congestions and sloughing of the contiguous skin; — effects which are always to be dreaded when it is found necessary to apply leeches to weak scrofulous children, greatly debilitated by confinement within the walls of an hospital, or low, damp, obscure, ill-ventilated dwellings.

The occurrence of mortification in scorbutus affords another striking example of the influence of general debility in the production of this disease. Portions of the skin often become gorged with blood, die, and slough, without our being able to discover that these parts have received any previous injury. The prostrate condition of all the functions of the economy, indicated by an unwillingness or the incapability to move; the feebleness of the pulse, the fluidity of the blood, and the imperfect state of nutrition in the worst forms of this disease, convert, as it were, the natural and healthy influence of physical agents into a means of destruction. Even the mastication of the food necessary for the support of those affected with this disease, cannot be performed unless at the risk of inducing mortification of the gums, and other soft parts of the mouth. The sloughing of these parts from this cause is sometimes very extensive, accompanied by a continual oozing of blood, and occasionally terminates by the loss of the greater part of the teeth, and even portions of the alveolæ. For a more detailed description of the varieties of form, extent, progress, and termination, as well as the treatment of this form of sphacelus, we must refer the reader to the article Scorbutus.

There is one other form of sphacelus from general debility which requires to be more particularly noticed in this place. It is that which has received the names of *noma; cheilocace; stomacace gangrænosa seu maligna; necrosis infantilis*, [*cancrum oris, gangrænopsis, gangrenous stomatitis*]; *pourriture des gencives; gangrène scorbutique aux gencives; wasserkrebs der kinder; gangrenous aphthæ; water-canker*. The gangrene and sphacelus which have been described under these various appellations occur generally in infants, and in children from two to five years of age, attack the mouth and cheeks, and the external parts of the female organs of generation. Their occurrence in the mouth may be owing to the presence of several diseased states of the mucous follicles, mucous membrane, or walls of this cavity. Thus gangrene and sphacelus may follow inflammation of the follicles or mucous membrane of the mouth, the inflammation being limited to these parts, as in follicular aphthæ, or combined with pharyngitis, scarlatina, small-pox, or scorbutus, examples of which will be found under these several heads. But the form of mortification to which we wish to direct the attention of the reader occurs in the parts which we have named without being preceded by any of these lesions. It commences, however, in the mouth, in the mucous membrane, and, perhaps nearly at the same time, also in the cellular tissue, generally of one, rarely of both cheeks. The general and local phenomena of the disease have been well described by Baron, (Mém. sur une affection gangréneuse de la bouche, Bulletins de la Faculté, 1816,) Isnard, (Dissertation sur une affection gangréneuse particulière aux enfans, Paris, 1818,) Billard, (Traité des Maladies des Enfans, &c.) Richter, (Der Wasserkrebs der Kin-

der, Berlin, 1828. Journal des Progrès, &c. tome iii. 1830,) and others, of which the following are the most important.

Symptoms.—In the first stage of the disease, the mucous membrane of one of the cheeks presents in some cases a small superficial ulcer without pain or discoloration. Sometimes there may be two or three ulcers, seldom more. In other cases, instead of an ulcer, a small whitish or yellowish grey spot appears on the mucous membrane, which sloughs, and gives rise to an ulcer similar to the former, or presenting the same colour as the slough by which it was preceded. It is not certain whether the disease commences by ulceration or sphacelus of the mucous membrane, but we are inclined to believe that it commences by the latter process. But, however this may be, there is observed nearly at the same time a greater or less degree of tumefaction of the cheek, opposite the ulcer or slough of the mucous membrane, which increases with great rapidity, and soon extends to the eyelids and lips. The skin of the swollen parts is pale and glistening, resembling wax, hard towards the centre of the swelling, and more or less elastic. A copious discharge of fluids takes place from the mouth, consisting at first of glairy saliva, and afterwards of a dirty sanies, which give a strong offensive odour to the breath. There is no pain in the cheek, little or no increase of its temperature; and so little are the functions in general disturbed, that children affected with the disease in this stage are sometimes able to amuse themselves with their companions, and partake of their ordinary meals without any apparent inconvenience.

The commencement of the second stage is marked by the appearance of a dull yellowish grey discoloration of the skin on the centre of the swollen cheek, where it is hardest, and opposite the sphacelated mucous membrane of the mouth. The portion of skin thus discoloured soon becomes black, and sloughs; the whole substance of the cheek undergoes the same successive changes, and in the course of a few days, sometimes less than a week, the cheek, lips, and eyelids are converted into a soft putrid mass, which, falling off, destroys sometimes nearly the whole of one side of the face, lays open the cavity of the mouth, and exposes the gums in a state of sphacelus, the inferior and superior maxillary bones denuded or necrosed, and deprived of their teeth. In milder forms of the disease the sphacelus may be arrested before it has proceeded far in breadth or depth, or after it has destroyed only a limited portion of the cheek and lips, and without having attacked the bones. The general symptoms which accompany this the last stage of the disease, are sometimes so mild, so disproportioned to the local ravages of the disease, that one cannot help being struck with astonishment. There is even a craving for food, which the little victims devour with greediness and apparent relish, and which they continue to do even until within a few hours of their death. The intellectual faculties are seldom much affected. In other cases there are from the commencement a low state of fever, a weak quick pulse, heat of the skin, thirst, and loss of appetite. The fatal termination of the disease is likewise sometimes announced by a state of great prostration and colliquative diarrhœa, excited probably by the absorption of the putrid fluids, and their passage into the stomach and intestines When this form of mortification attacks the labia, it presents the same local and general phenomena, commencing with a sloughing or ulcerated state of the mucous membrane of these parts, accompanied with the same kind of tumefaction and discoloration, and terminating in sphacelus, which spreads with great rapidity, and destroys to a greater or less extent the neighbouring parts.

From the above description of this form of mortification, little doubt can be entertained as to its being a disease arising in that state of general debility which we have already endeavoured to explain. All the phenomena which it presents are also so characteristic, that it is not likely to be confounded with any other disease except malignant pustule, from which, however, it may be distinguished, as has been observed by Rayer and others, from the latter disease, when it affects the cheek, always commencing on the external surface.

Prognosis.—The prognosis of this disease is extremely unfavourable when it attacks children in hospitals, for few of them survive its ravages. We have, however, seen its progress arrested in a few instances, and in two cases the patient survived the loss of a large portion of the cheek and a part even of the inferior jaw. When children are placed in more favourable circumstances, where they enjoy fresh air and receive all the care that their situation requires, the remedial means are more efficacious, and the mortality of the disease less considerable.

[Even in hospitals, however, the deaths are not always in very large proportion. In the year 1838, of twenty-three cases, treated in the children's asylum of the Pennsylvania Hospital, nineteen recovered, and four proved fatal. (See the writer's *Practice of Medicine*, 2d edit. i. 34: Philad. 1844.) It would seem to be frequently complicated with pneumonia. M. Baudelocque, indeed, asserts that the complication is invariably found to exist; and MM. Barthez and Rilliet (*Traité Clinique des Maladies des Enfants*, i. 152: Paris, 1843,) met with it in every instance that came under their notice.]

Treatment.—As soon as the disease is perceived, the slough or ulcers of the mucous membrane, whether of the labia or mouth, are to be touched with a mixture composed of equal parts of honey and muriatic acid, or with the latter alone. But when the disease is more advanced, when the swelling is considerable, and the stage of sphacelus has arrived, Mons. Baron strongly recommends that the sphacelated tissues be divided, and the actual cautery, heated to whiteness, carried deep into their interior. (Loc. cit.) This treatment is said to be by far the most successful. Marjolin states that he has employed it with complete success, and also the nitrate of silver, in the state of powder, introduced into the incised sphacelated tissues. (Dictionnaire de Médecine, tom. x.) The muriate [chloride,] of soda is also an efficacious remedy, as it is found not only to arrest the progress of the disease, but likewise removes the stench by which it is accompanied.

[Liquor Potassæ, nitric acid, pyroligneous acid,

chlorine and tincture of chloride of iron, have likewise been advised, with or without incisions; but the caustics or excitants that have met with most favour, have been sulphate of copper, and nitrate of silver in the solid form, so as to produce an eschar over the whole of the sloughing parts. Dr. B. H. Coates (*North Amer. Med. & Surg. Journal*, 1826,) recommends the following application: *Cupri sulph.* ʒij., *Cinchon.* pulv. ʒss., Aquæ, f.ʒiv. M.; or the cinchona may be omitted. When sloughs have formed on the cheeks, the yest cataplasm, or poulticcs containing powdered bark, or chlorinated lime, or chlorinated soda, or pyroligneous acid, may be applied to the part previously washed with any of the lotions already mentioned.]

Every precaution ought to be employed to prevent the putrid fluids from being swallowed, and perhaps the best means of doing so is to wash out the contents of the mouth with a decoction of bark, or a gargle of muriatic acid and honey; and to prevent them accumulating, the patient should be made to lie on the affected side of the face, so that they may find a ready exit. The swollen parts should be covered with cloths dipped in an aromatic fomentation, and occasionally rubbed with the liniment of ammonia, or other stimulating substances. Although this disease originates in a state of general debility, the local treatment which we have pointed out is regarded as the only certain means of arresting its progress. The operation of general remedies is too slow to have any control over a disease which proceeds with such rapidity, and therefore general remedies must be regarded only as auxiliaries. They should consist of nutritious fluids and small quantities of wine, but the administration of the latter in particular must be regulated by the state of the digestive organs, which in this disease are often greatly disordered and highly irritable, and therefore require to be remedied by means suited to the kind of derangement which they may present in each individual case.

[Cinchona, especially, and the salts of its active principle, quinia, may also be freely administered, and iodide of iron offers prospect of advantage. Recently, the internal use of chlorate of potassa has been highly extolled by Dr. Henry Hunt (*Medico-Chirurgical Transactions*, xxvi. 142), in the dose of from ℈j. to ℈ij., in 12 hours, according to the age of the patient.]

II.—Mortification from the violent operation of mechanical, chemical, and physical agents.

The mechanical agents which occasion mortification are violent blows and contusions of various kinds; the chemical, powerfully stimulating substances; and the physical, extreme heat and cold. All these agents produce the same ultimate effect in the part of the body which has been submitted to their influence; that is to say, they deprive, to a greater or less extent, such a part of those properties on which its existence depends. The effect of a contusion produced by a heavy weight falling upon or passing over a part of the body, may be partial or complete death of such a part; and that produced by a bullet, instantaneous death of the soft parts, to a certain extent beyond the limits of the solution of continuity which it occasions in its passage through them. Strong stimuli, intense heat and cold, may operate precisely in a similar manner. The destructive effects of these agents are, however, not always the same in degree or extent, nor are they always produced in precisely the same manner. In one case there may be no gradation of change, no intermediate state of disease which separates these destructive effects from the previous healthy condition of the tissues in which they are produced: local death may be the immediate consequence of the violent operation of such agents. In another, the vitality of the part which has been exposed to the operation of these agents is not entirely destroyed. In this case the part may be regarded as in a state of gangrene; and in the former, in a state of sphacelus. In the present case it may or may not be susceptible of recovery, the result being dependent on the subsequent changes which may take place in the affected part itself, or in those parts with which it is connected. Congestion and inflammation are the changes which always take place, to a greater or less extent, in gangrene of this kind. If they can be prevented from taking place, moderated or removed when present, the suspended functions of the part may be restored; otherwise the gangrene terminates in sphacelus.

The state of congestion and inflammation to which we have just alluded originates in opposite states of the vascular system. The congestion takes place in the gangrened tissues, because of the vessels being deprived of those properties by means of which they were enabled to propel the blood through them. They have ceased to contract, and consequently the blood, although carried into them in the usual quantity, accumulates in, and distends them to a greater or less extent. On the contrary, the blood-vessels situated beyond the gangrened tissues having received little or no injury, are stimulated either by the presence of the disease acting as a foreign body, or have been previously excited by the cause which produced the gangrene, to such a degree as to give rise to an increased influx of blood, to an increase of the sensibility and temperature, and other phenomena of inflammation. Under these circumstances the remaining vitality of the gangrened part is soon destroyed, and consequently a state of real death produced.

However important it may be in a practical point of view to be fully acquainted with all the changes which take place in the structure and functions of a part which has been submitted to the violent operation of mechanical, chemical, and physical agents, we shall not enter into a more detailed description of them than may seem necessary to our present purpose, as this part of our subject belongs almost exclusively to the department of surgical pathology.

We may, however, observe,—1. that the degree and extent of these changes of structure and function are proportioned to the intensity of the agent by which they have been produced, the degree of energy with which it has acted, and the duration of its operation;—2. that the recoverable or irrecoverable condition of the structure and functions of the injured part are essentially deter-

mined by similar modifications of the efficient cause;—3. that congestion or inflammation are subsequent changes depending on the primary lesion or its agent, always effects and complications but never causes of the disease, unless secondarily and under those circumstances to which we have alluded, that is, when the part is left in a recoverable state, or in a state of gangrene;—4. that, therefore, mortification from the violent operation of mechanical, chemical, and physical agents, differs from that produced by inflammation, an obstacle to the circulation of the blood, and local and general debility; the disease, in the former case, consisting essentially in a simultaneous lesion of all the elements; in the latter, of one element only of the part in which it is produced. There are, no doubt, slight exceptions to these general conclusions; but considering them in a general point of view, they appear to us to be drawn from a series of facts sufficiently broad and distinct to render it necessary to consider apart these two forms of mortification, independently of the advantage of doing so in a practical and scientific point of view.

For the reason before stated, we shall confine the few observations which we have still to make on this form of gangrene, to some of the more remarkable phenomena which it presents when produced by the action of intense heat and cold on the external parts of the body, and strong stimuli on the digestive mucous membranes.

1. **Mortification from Intense Heat.** — The effects of intense heat on the surface of the body are a greater or less degree of excitement, a temporary or permanent suspension of the functions of the part to which it has been applied; or in other words, there is produced a state of inflammation, gangrene, and sphacelus. The states of inflammation and of gangrene do not require to be described, as the phenomena which they present in the present case do not differ materially from those which accompany the same changes when they occur without any obvious cause, if we except the rapidity of their progress, and also the more sudden and extensive development of phlyctenæ, bullæ, or blisters, particularly when the heat is applied by means of a fluid. The state of sphacelus produced by the direct application of heat presents several very characteristic appearances. The skin is of a yellow, grey, brown, or black colour; dry and hard; sunk below the level of the surrounding surface, and quite insensible. These are, sometimes, the only appearances which are at first perceived to follow the action of intense heat, and are certain indices of the complete death of the skin to a greater or less depth. The deeper-seated tissues may also be deprived of their vitality, but to what extent cannot be determined by any change which the cutis may have suffered. The inflammatory redness which succeeds to this state appears almost immediately, and indicates by the rapidity of its course and the peculiar colour which it assumes, the extent both of the gangrene and sphacelus, the existence of which could not be determined by any previous change of the cutis produced directly by the heat. We do not wish it to be understood that we are speaking of gangrenous inflammation. The degree of inflammation produced by intense heat may, certainly, be such as to give rise to mortification; but in the present case we wish to show that both stages of this disease may be, and often are, the immediate effects of the physical agent in question, and, consequently, whether capable of being detected or not by any peculiar change in the affected part, precede the inflammation to which they are often ascribed.

The extent of the sphacelus may be said to be always increased by the subsequent inflammation; and parts that were only in a state of gangrene are, by means of it, converted into a state of sphacelus; and hence the necessity of preventing the extension or modifying the violence of the inflammation which succeeds to burns or scalds.

Whether the state of sphacelus may have been produced by the action of the heat or the subsequent inflammation, the limits of the disease are seldom defined before the end of a week or ten days. The dead are then separated from the living parts, and an abundant suppuration takes place from the denuded surface. The solution of continuity is often imperfectly repaired in consequence of the exuberant production of granulations, which, instead of acquiring the organization of the cutaneous texture, assume that of contractile tissue, which often gives rise to great deformity of the parts with which it is connected. The general as well as the local effects of intense heat in case of burns and scalds, are proportioned to the extent and violence of the injury produced by this agent. They are characterized by excessive pain, great mental agitation, and extreme thirst; the pulse is rapid and hard, the skin hot, and the secretions in general are diminished in quantity.

If a remission of these symptoms does not take place soon, the pulse becomes small and feeble, and the skin covered with a cold sweat; the sufferings of the patient are announced by wild delirium; or he sinks into a state of stupor, accompanied with convulsion. In some cases of violent and extensive burns, these symptoms make their appearance almost immediately after, and are followed by death in the course of a few hours.

The general symptoms are greatly modified by the situation of the burn or scald, independently of the age, constitution, and temperament of the patient. For it has been observed that a burn of any of the extremities gives rise to much less constitutional disturbance than a burn of the walls of the chest or abdomen, although it may be of the same degree and extent in each of these parts. The greater functional derangement in the latter case depends, no doubt, on the vicinity of the disease to the important organs contained in the abdominal and thoracic cavities.

It has been asserted that the mucous membranes, and especially the digestive mucous membrane, are not only inflamed in all cases of burns of any considerable extent, but that the secondary fever that follows is chiefly owing to this lesion of the digestive organs. With regard to the latter statement, nothing can be more obviously erroneous, as the intensity of the pain in all such cases is in itself sufficient to produce the secondary fever. However far the former statement may be correct, we have not had sufficient opportunity to determine. We have seen the respiratory and mucous membranes red and vascular in one fatal

case, the patient having died at the end of four days. In two other cases this membrane in both of these organs was pale, and without any appreciable lesion. These two patients were females, and had the inferior half of their bodies severely burnt, from their clothes having caught fire: both of them lived seven or eight days. It is possible that the difference in the duration of the disease in these cases may have had some share in effecting the difference observed in the state of the mucous membrane after death. But it is of greater importance to observe that the secondary symptoms were equally severe in all the three patients.

With regard to the local and general treatment of burns and scalds, we shall only observe that in the latter, antiphlogistic measures, carried to the extent which the individual case demands, must always be had recourse to, although the secondary fever, when it occurs at an early period, and depends more on the shock which the system has received and the violence of the pain, is but little under the control of such measures. More benefit is derived from the administration of anodynes, and the use of those means which the surgeon has found to be most successful in allaying the local heat and pain of the injured part. Opiates are particularly useful in abating the great nervous excitement which accompanies this form of fever, and in procuring a temporary respite from suffering.

It is of much importance to distinguish between the febrile excitement which immediately follows the injury, and the secondary fever which is the consequence of the subsequent inflammation. As in the latter case, general bloodletting is always more or less useful. The same indication is pointed out when inflammation of an internal organ has taken place, although leeching and cupping are oftener to be preferred to the lancet. In stout young persons of a sanguine temperament it may be necessary to employ both.

2. **Mortification from Cold.**—The local and general effects of intense cold are, in many respects, very similar to those produced by intense heat. If the degree of cold be not very great, the circulation and temperature, of the skin for example, when submitted to its influence, are increased, as is shown by this tissue assuming a redder colour, and feeling warmer than before. On the contrary, if the cold be very intense, it may not give rise to any appreciable degree of local excitement; the vitality of the skin, and even of the deeper-seated tissues at the same time, may be either greatly reduced or entirely destroyed by the direct operation of this physical agent. There is, however, this difference between the local effects of heat and cold, viz. that the former may produce complete disorganization of the tissues submitted to its action; whereas the latter never produces such a change. In the former the local redness rapidly increases, in the latter it rapidly diminishes; and in the same manner does the sensibility increase and decrease under the influence of these agents respectively. (We are now speaking of the immediate, and not the subsequent effects of cold.) The general effects, or functional disorder produced by the immediate operation of cold, are very different from those produced by heat. If the cold has been limited in its operation to the extremity of a limb, complete death of the part may ensue without any general functional derangement being induced. But if the whole body has been exposed to its operation, every function becomes depressed, and a state of lethargy soon succeeds, from which the patient is often not to be roused, either by the entreaties of his friends or the best directed efforts of the physician.

The symptomatic fever which follows the local effects of cold does not take place until inflammation has succeeded to these effects, for it depends exclusively on the presence of this morbid state; and hence the similarity said to exist between the symptoms of mortification from cold, and those of mortification from heat. It is, in fact, only after the occurrence of inflammation that the local and general symptoms of mortification from these two causes acquire a striking similarity in kind, if not in degree.

Although a state of gangrene and sphacelus of a limb or a portion of a limb may be induced by the direct operation of intense cold, we may not be able to determine the existence of either until inflammation has taken place. It is, however, said that the toes and fingers have been seen to fall off, having been deprived of life on account of the intensity of the cold. But by far the most frequent occurrence of mortification is when a frozen limb is exposed to natural or artificial heat, as before a fire or during thaw. The blood that was before frozen thus regains its fluidity, and gangrene and sphacelus, if they were not previously, are now more or less rapidly induced. Under these circumstances, the skin assumes a dark red or livid colour, where it is in a state of gangrene or sphacelus, and the neighbouring skin acquires an erythematous blush, accompanied with a prickling or tingling sensation, and a feeling of weight or stiffness in the limb. By-and-bye phlyctenæ appear on the inflamed part of the limb, and grey, livid, or black spots on that part of it which is in a state of sphacelus. Then also putrefaction commences, and extends till its progress is arrested by the adhesive inflammation. In this kind of mortification, as well as in every other, the extension of the sphacelus depends much on the degree of the subsequent inflammation, to subdue and still more to prevent the occurrence of which every means ought to be promptly and sedulously employed.

The treatment of a frozen limb, for example, consists in rubbing it with snow or pounded ice, in order to re-establish gradually its sensibility and circulation, and afterwards the use of a circular roller carried from the toes upwards, the good effects of which depend on the obstacle which it opposes to the accumulation of the blood in the limb, and to the distension and swelling to which the presence of this fluid and the subsequent effusion of serosity give rise.

3. **Mortification from Stimuli.**—The stimuli included under the present head, and which give rise to mortification, are those which exercise a chemical influence on the tissues with which they come in contact. The nitric, muriatic, and sulphuric acids may be cited as furnishing us with examples of chemical stimuli which produce local death when they are applied to the skin or

mucous membrane of the digestive organs. The local effects of these substances resemble very much those produced by intense heat. Like the latter physical agent, they instantly destroy, to a greater or less depth, when strong, the cutaneous and mucous tissues. In both cases, the vitality and texture of these tissues are destroyed, and the functional derangements of the economy are also very nearly the same, particularly when the former have been applied to the digestive mucous membrane. The functional derangement, too, which follows the action of these chemical stimuli, does not arise in consequence of absorption, but, as is the case in intense heat, from the sudden shock which the nervous system receives at the moment they are applied, and the state of excitement of this system from the inflammation to which they give rise. Instead of a state of complete local death, or sphacelus, we may have as the result of their action, when diluted, a state of gangrene, or simply inflammation, and which may, as in similar states produced by other causes, terminate in sphacelus. A state of sphacelus is, however, the far more frequent effect of their immediate operation in the undiluted state, to which inflammation occurs as a subsequent change, and which seldom proceeds, unless in the mucous membranes, beyond that degree necessary for the elimination of the dead part.

The local effects of these chemical stimuli are not often confined to one portion of the cutaneous or mucous tissues; they are generally perceived on several portions of both, the form and extent of which are subject to great variety, more particularly in the stomach; the states of vacuity and fulness, or the nature of the contents of this organ, modifying, in a greater or less degree, both of these local circumstances.

The changes of colour which indicate that local death has been produced by these chemical stimuli are well known; they are either yellow, yellowish brown, brown, or black, changes which seem to depend much on the quantity of blood contained in the part, and the strength of the acid which has been applied to it.

Perforation of the stomach, giving rise to a communication between the cavity of this organ and that of the peritoneum, is not unfrequently the consequence of the introduction of these acids into this organ, and we believe that when it does take place, it is generally soon after their introduction, and before the peritoneal inflammation which ensues has been sufficiently long established to furnish coagulable lymph, and unite some neighbouring organ with the stomach, opposite that part of it which has been acted upon by the acid. Under these circumstances, therefore, the perforation is not the consequence of the separation of the sphacelated tunics of the stomach by their subsequent inflammation, but is the result of their immediate and complete destruction.

There are several important points connected with this part of our subject which merit particular consideration, more particularly the change of colour and consistence to which chemical stimuli give rise in the mucous membrane of the stomach, to the former of which we have already alluded, but into the consideration of which we do not think it necessary to enter in this place, as we have already insisted on similar changes in the article Melanosis, where we have endeavoured to show that they may be produced by the action of the gastric acid after death, and present appearances so similar to those of the former as to lead the toxicologist and medical jurist to commit the most serious mistakes. As these chemical stimuli are classed among the poisons, we refer the reader to the article Toxicology for a description of the symptoms to which they give rise, and the treatment which they require.

III.—Mortification from the deleterious influence of certain poisons.

The poisonous substances which we propose to include under the present head are those which are derived from the animal and vegetable kingdoms. Some of these substances are natural, others morbid products. The former consist in a peculiar healthy secretion of certain animals, which is capable of producing disease or death in other healthy animals, and for which we have no distinctive appellation except the vulgar term of *venom*. The latter, derived from the animal kingdom, are generated by a state of disease of the animal solids and fluids, are capable of producing the same morbid state to which they owe their formation, when communicated, directly or indirectly, from one animal to another, and are termed *virus*. We have no specific denomination for the deleterious agent generated by the decomposition of animal matter, and by that diseased state of rye which gives rise to mortification.

Mortification arising from these different sources may be considered with advantage under the following heads:—1. mortification from a deleterious agent generated in healthy animals; 2. mortification from a deleterious agent generated during the decomposition of animal substances, and in animals in a state of disease; 3. mortification from a deleterious agent generated in vegetables in a state of disease.

1. Mortification from a deleterious agent generated in healthy animals.—We have already said that a peculiar healthy secretion of certain animals is capable of giving rise to mortification, when directly applied to the body of another healthy animal. The most striking examples of this are met with in the effects which follow the bite of the *cobra di capella*, the rattlesnake, and the viper. When the poison of these animals is inserted into the cutaneous and cellular tissues of one of the limbs, the most acute pain is produced, which rapidly extends in both directions towards the extremities of the limb; the cellular tissue becomes œdematous, much swollen, and hard. If there be any redness of the skin around the wound, it is of short duration, and is succeeded by a livid discoloration, which increases in extent, followed by the formation of phlyctenæ, and diminution of the temperature of the affected part. The hard œdematous swelling of the skin and cellular tissue then becomes soft, crepitates when pressed, and a sanious discharge, of a fetid odour, runs out from the wound. During the short time these local changes are taking place, the functional derangement produced by the absorption of the poison proceeds with extreme rapidity, and it may terminate in death in the

course of a few hours. Almost immediately after the insertion of the poison, a sense of great oppression is felt in the region of the heart: the respiration becomes laborious; there is great pain in the head, or vertigo, and frequently pain in other parts of the body, but particularly in the stomach and intestines, accompanied with vomiting and diarrhœa: vision is also sometimes much impaired, and the pulse small and intermittent. As the influence of the poison becomes more extended, to these symptoms are added extreme debility, great anxiety, the most unquenchable thirst, cold sweats, hiccup, and frequent fainting fits: the skin assumes a sallow, jaundiced aspect, and the breath becomes extremely offensive. Such is a general description of the local and general effects which follow the insertion of the poison of these animals into the cutaneous and cellular tissues. Although the local treatment is strictly surgical, we may state here that it consists, as recommended by Celsus, and very recently by Sir David Barry and others, in the application of a ligature to the limb between the wound and the heart, so as to arrest the venous circulation and intercept the poison; the use of the cupping-glass, and the actual cautery. Various topical remedies are recommended, and are said to have been employed with success. Indeed, the local appears to be much more successful than any general treatment that has yet been devised, in arresting the progress or in preventing the baneful effects of the poison of these animals. The liquor ammoniæ is regarded as the best internal remedy that can be employed. It is also said that stimulating sudorifics have been found useful; but it does not appear that much reliance is to be placed on the use of internal remedies when the poison has once entered the system, and when it possesses such a degree of virulence as to destroy the vitality of the part to which it is originally applied. It is to such cases alone that our observations apply, as in milder cases mortification seldom occurs in consequence of the direct application of the poison.

2. **Mortification from a deleterious agent generated during the decomposition of animal substances, and in animals in a state of disease.**—The production of mortification from a septic agent, generated during the decomposition of animal substances, or in animals in a state of disease, being introduced into the blood or applied to the surface of the body or of sores, is by no means a rare occurrence. The most obvious and frequent examples of mortification of this kind are met with in the bodies of those who have died from mortification of some external part of the body, from whatever cause arising. Mortification of a portion of a limb, succeeding to inflammation, to a mechanical injury, to an operation, is often followed by mortification of some internal organ. The same may be said of mortification of one internal organ, giving rise to mortification of another internal organ, although it is by no means so frequently observed as in the former case. We have seen a considerable number of cases of gangrene and sphacelus of internal organs originating in the existence of similar states on the external surface of the body. That such is frequently the origin of mortification of internal organs there cannot be the slightest doubt; for it occurs when this disease affects an external part of the body from inflammation, a surgical operation, or other causes to which the internal organs, which are afterwards found to be in a state of mortification, were in no way whatever subjected. The septic principle is carried into the blood, and appears to give rise to a state of gangrene or sphacelus, without these being preceded by any perceptible intermediate change. For when we examine the organ thus affected, we do not perceive any of those changes which accompany inflammation, such as red induration or suppuration; nor are there any symptoms during the life of the patient which indicate the presence of a local disease. The lungs and liver may be extensively affected without the functions of either undergoing any modification which indicates the existence of such a disease. They are, however, modified, as well as those of every other organ of the body, by the contaminated state of the blood, to which we have already ascribed that peculiar assemblage of symptoms which make their appearance at the close of the fatal termination of sphacelus.

The morbid appearances of this kind of mortification of internal organs present several peculiarities. The tissues of the organ do not, as we have already said, exhibit any of those changes which constitute the anatomical characters of inflammation. They are, on the contrary, found to present those appearances which we observe on a part of the external surface of the body to which a virulent poison has been applied, viz. a circumscribed dull deep-red, livid, brown, or black colour, in which state they feel firmer than natural; or they are of a dirty grey colour, of a soft pulpy consistence, or entirely decomposed and transformed into a grey or reddish-brown fluid of the consistence of pus, around which the other tissues may not present any material alteration. These appearances are most frequently observed in the lungs and liver. They may exist in several points of these organs at the same time; may occupy an extent of surface varying from the fourth of an inch to two or three inches; and are much more frequently situated towards the external surface, than in the central parts of these organs. In the lungs they are generally seen under the pleura, and if the patient survives a certain length of time the contaminating influence of the poison to which they owe their origin, the pleura sloughs, and pneumothorax is produced. We have seen two examples of this termination of sphacelus of the pulmonary tissue and pleura, arising in, or connected with, sphacelus of the ankle-joint in one patient, and in another with sphacelus of the larynx.

The production of gangrene and sphacelus from a septic agent generated in a state of disease is no less conspicuous in what is called **hospital gangrene.** Whatever may be the causes of hospital gangrene, this local disease may be communicated by means of the fluids of the diseased part being brought in contact with the surface of common sores, a scratch or prick, and, it is said, with the healthy skin. When the disease is thus produced, for example in a sore, the surface assumes a paler or livid aspect, becomes swollen and painful, and covered with a viscid

grey matter tinged with specks of blood. The surrounding integuments soon present the same appearances, are converted into dirty-grey spongy sloughs, the extent of which, as well as the progress of the disease, is marked by the preceding discoloration, which is often of an erysipelatous character, affecting at the same time the skin and subjacent cellular tissue, and thence the adjoining lymphatic glands, which are also destroyed in the manner above stated. But although the state of sphacelus be often preceded by an erysipelatous redness, the separation of the dead parts is always accompanied by more or less hemorrhage, which shows that the plastic property of the blood by means of which hemorrhage is prevented, as well as the vitality of the solids, is destroyed in this kind of mortification. Dr. Hennen, in his *Principles of Military Surgery*, states that in the last stage of the disease there is a bloody oozing from the surface of the denuded parts; that in lifting up the edge of the flabby slough, the probe is tinged with dark-coloured grumous blood, with which its track becomes immediately filled, and that at this period of the disease repeated and copious bleedings take place which rapidly sink the strength of the patient. The sloughs, whether falling off spontaneously, or detached by art, are thickly studded with specks of arterial blood; and when hemorrhage takes place from an artery which it is necessary to tie, and which is ruptured by the ligature, the application of the tourniquet or other pressure is employed in vain, for while it checks the bleeding, it accelerates the death of the limb, which becomes frightfully swollen and horribly fetid.

The constitutional symptoms of this kind of mortification sometimes precede the local affection, at other times do not make their appearance until it is fairly established. But however this may be, they are characterized by greater or less derangement of the digestive functions, a feeble and quick pulse, and great weakness of mind and body. "Men," says Dr. Hennen, "who had borne amputation without a groan, shrunk at the washing of their sores, and shuddered at the sight of a dead comrade; or even, on hearing the report of his death, predicted their own dissolution, and sunk into sullen despair." The fatal termination of this frightful form of mortification is announced by extreme prostration, vomiting, hiccup, involuntary dejections, and coma.

The treatment of the present form of mortification will depend much on the state of body and mind of the patient, and the situation in which he is placed. When it occurs in a healthy individual, his removal from the place in which it was communicated to him, and the topical application of those remedies (the concentrated acids or actual cautery) which are now found to be most efficacious in arresting the progress of the disease, will in general effect a speedy cure. In such means, also, consists the most essential part of the treatment which the situation of those patients will allow in whom the disease occurs spontaneously, that is to say, without any direct cause, and whose mind and body have suffered from the injurious influence of disappointment and privations of various kinds. Cheering prospects, wholesome food, and change of situation, are well known to be the most effectual means of preventing and checking the ravages of this disease in hospitals, or other situations, in which a greater or less number of patients are confined, and without which all our remedies are often entirely useless, or procure only a temporary or partial benefit.

The next form of mortification produced by a septic agent generated by disease is that which is called **pustule maligne**, or *charbon*, by the French, and *milzbrand*, by the Germans. By some pathologists this disease is believed to originate in horned cattle, among which it sometimes prevails epidemically to a very great extent, and that when it occurs in man, it is always derived from such animals. By others it is said to occur *sporadically* in persons who have no connection, either directly or indirectly, with animals so diseased. Be this as it may, the important fact is, that a septic principle is generated in this disease, which possesses the property of communicating a similar disease from one animal to another and from person to person. Hence it is that herdsmen, butchers, and tanners, and all other persons who handle the skin, blood, and flesh of these animals, are those in whom the malignant pustule or carbuncle is generally observed. Enaux and Chaussier regarded the occurrence of the disease in such persons as strong proof that it was communicated to them by immediate contact; and in further support of this opinion, they adduce the facts that malignant pustule makes its appearance exclusively on those parts of the body which are usually uncovered, such as the face, neck, breast, and shoulders; the hands and arms, feet and legs; and that in general it is observed in such persons when it reigns endemically among cattle. (Enaux et Chaussier, Méthode de Traiter les Morsures des Animaux Enragés, &c. suivie d'un précis sur la pustule maligne. Dijon et Paris, 1785.)

Numerous examples are recorded of malignant pustule being communicated in the manner above alluded to, as well as of its being communicated to persons employed in dressing those affected with the disease. The blood appears to be strongly impregnated with the septic principle generated in this disease, for parts of the body on which this fluid has been deposited have soon after been affected with malignant pustule, and similar effects follow its injection into the veins, as was the case in the experiments of MM. Leuret and Hamont. (Journal des Progrés des Sciences Médicales, 1827.)

Those who eat the flesh are also often affected with an eruption of malignant pustules, and other symptoms similar to those which the animal from which the flesh was taken presented.

Malignant pustule commences in the form of a small vesicle, filled with a somewhat bloody serosity, accompanied with a circumscribed œdematous swelling of the skin and cellular tissue beneath it, which soon extends in breadth, followed by an erysipelatous redness of the skin. As the swelling increases, the skin acquires a glossy aspect, and presents here and there small and large phlyctenæ. The erysipelatous redness soon assumes a livid tint; the central portion becomes brown or black, hard and insensible, whilst the surrounding parts are tense and emphysematous. These changes

are produced with greater or less rapidity, and sometimes extend to a considerable distance, followed by extensive sloughing of the skin and cellular tissue. The local and general symptoms of malignant pustule resemble very much those which follow the bite of the viper, &c. which we have already described, and require nearly the same treatment.

Maurand (Histoire d'une Maladie très singulière, &c. in Hist. de l'Acad. des Sciences, 1766, i. 97) relates some cases of malignant pustule produced by the flesh or blood of over-driven cattle, although their bodies presented no appearance of disease. It would appear that the flesh of such animals may be eaten with impunity when cooked, but that if the blood or raw flesh be applied to the wounded skin, or even to the unbroken skin, diffuse cellular inflammation is excited, or malignant pustule produced, which frequently terminate fatally; and M. Dupuy states that the malignant pustule or carbuncle of cattle may be produced by applying to a wound the blood of an animal that has died of gangrene of the lungs. (Revue Médicale, 1827, ii. 488.)

The carbuncle of plague and the malignant pustule present precisely the same local characters as those which we have just described, and seem to owe their origin to a similar cause, viz. the development of a septic agent, and which in the former seems to be formed during the progress of the disease in which it is observed. The number of the pestilential carbuncles vary considerably, and are generally in proportion to the gravity of the disease which they accompany and in which they originate. Pestilential carbuncle, like malignant pustule, may be communicated by contact or inoculation; and it is said by Diemerbroëck and Desgenettes, may prove fatal without giving rise to the general symptoms of the plague. (*Diemerbroëck*, Tractatus de Peste, 1665. *Desgenettes*, Histoire Médicale de l'Armée d'Orient, 1802.)

There can be no doubt that a septic agent is developed during the decomposition of animal substances, apart from the living body, capable of producing mortification. This state, however, is always preceded by erysipelatous inflammation, which spreads with great rapidity and proceeds to a great extent, and followed during its progress by extensive sloughing of the skin and cellular tissue, and is accompanied by the same kind of general symptoms that characterize the action of all septic agents on the economy. It is difficult to say how far wounds received in dissection or in the inspection of dead bodies, and which are followed by diffuse erysipelatous and gangrenous inflammation, depend on the presence of a septic agent developed during the progress of disease, or after death. One thing is certain, that the frequency and severity of the disease which follows such wounds, have, so far as we can perceive, no connection with the ordinary changes of the solids and fluids produced by putrefaction; for the results of our own experience are in accordance with the generally received opinion, that it most frequently occurs after wounds received in the examination of recent bodies, and also in the bodies of those who have died of inflammatory effusions into the serous cavities. Nevertheless similar consequences follow pricks and wounds from putrid bones, and the contact of putrid animal matter with the abraded surface of the skin; and Cullerier says that gangrene sometimes attacks the penis of those persons employed to clean out the cesspools in Paris, if they are affected at the time with gonorrhœa.

It would appear that a septic agent is developed in various grains in a state of disease, but more particularly in rye, which, when used as an article of food, has frequently given rise to one of the worst forms of mortification. This form of mortification has, perhaps, been exclusively observed in various parts of the continent of Europe, and particularly in those districts of France, Germany, and Switzerland, in which rye forms the chief article of food of the inhabitants. In these and various other parts of the continent, the local and general effects of spurred rye, as it is called, have been observed and described by several physicians; but it was not till the year 1597 that they were traced to the internal use of that diseased grain. Since then, repeated epidemics have occurred, and always during rainy seasons, and which have prevailed most in places naturally moist and of a poor soil,—circumstances to which, in fact, the ergot or cockspur owes its origin. We shall not stop to inquire into the causes of the spur in rye, and besides shall confine ourselves to a general description of its effects. The effects produced by the use of spurred rye as an article of food are very various. In some individuals the influence of the poisonous ingredient is chiefly exerted on the brain and nervous system, the most remarkable symptoms being vertigo, dimness of sight, pain, loss of sensibility, cramps and convulsions, yellow discoloration of the skin, thirst and feeble pulse. These symptoms are greatly modified in degree in different individuals, and are sometimes slow and at other times very rapid in their progress. In the most acute form of the disease death may take place at the end of one or two days, preceded by dreadful cramps and convulsions of the whole body. Even in the milder cases, the convulsions are more or less severe towards the fatal termination of the disease; and hence this form of the disease is called **convulsive ergotism** by French writers, and is vulgarly denominated in Germany *Kriebelkrankheit*, or creeping sickness. In other individuals, placed apparently in similar circumstances, the most remarkable effect which follows the operation of the same septic agent is gangrene or sphacelus of certain parts of the body. Hence this form of the disease has received the name of **gangrenous ergotism,** *necrosis ustilaginea, seu epidemica.*

The local, like the general effects of spurred rye, present considerably variety. The following description of them taken from the works of those authors who have witnessed the disease in various parts of the continent, contains the principal forms under which they have appeared. In one class of patients seen by Dodart, the disease was characterized by vertigo, a malignant form of fever, great drowsiness, and gangrene of the inferior extremities. The gangrene was preceded by a sensation of numbness in the legs, which became afterwards painful, slightly swollen, but not inflamed. The skin was cold and livid, and

the sphacelus commenced in the centre of the limb, and did not reach the skin till some time after. (Journal des Savans, 1676.)

In a second class of patients, in which the disease was observed by Noël, surgeon to the Hôtel Dieu of Orleans, the sphacelated parts were dry, livid, or black: these appearances commenced in the toes, and gradually extended sometimes as far as the thighs. In some the sphacelated parts separated spontaneously; in others the progress of the disease was arrested by scarifications.

Lang, who observed the gangrenous ergotism in Luzerne, Zurich, and Berne, says that the disease commenced with lassitude and a sensation as of insects creeping under the skin, without fever. Soon after, the extremities became cold, pale, wrinkled, and benumbed, and at last quite insensible and incapable of motion; afterwards acute pain was felt, referable to the central parts of the limbs, which was exasperated by heat and mitigated by cold applications; there was then, also, fever and headach; the pain extended from the hands and feet to the shoulders, legs, and thighs; and lastly, the affected parts became dry, shrunk, and black, and dropped off at the joints. Entire extremities were thus separated from the body without hemorrhage. Many patients lost both legs, several the arms, and a few both legs and arms. (Descriptio morborum ex usû clavorum secalinorum cum pane, 1707.) In other cases, the chief symptoms were, at first, spasmodic contractions of the limbs, afterwards great weakness of mind, voracity and dyspepsia, which generally terminated in fatuity or sphacelus. (Rust's Magazine, xxv. to which the reader is referred for a detailed account of the local and general effect of spurred rye.) The parts most frequently attacked with gangrenous ergotism are the inferior extremities. Men are more subject to the disease than women, and children and old people than adults.

From the above description of the local and general effects of spurred rye, it is by no means easy to say in what manner this poisonous article of food operates so as to produce mortification. One thing, however, appears certain, that it is not by an inflammatory process of the part which becomes the seat of the disease. That cessation of the circulation and loss of the sensibility and motion of the limb observed to take place at an early period of the disease, are not the consequences of inflammation, is clearly proved by the nature of the local, if not the general symptoms which we have detailed. All these local changes appear to be produced as direct consequences of the spurred rye, acting through the medium of the blood or nervous system, or both at the same time. For we have seen that the dead parts are separated without hemorrhage, and it is stated that the blood, when taken from a vein, is dark and so very thick that it only oozes out from the orifice of the wound.

In several animals which died after having been fed for some time on spurred rye, and who presented several of the symptoms already mentioned, gangrenous spots are said to have been found in the stomach, intestines, and liver. But the morbid anatomy of this disease is extremely imperfect, and does not enable us to offer any explanation either in regard to the nature of the disease itself or its complications; or to suggest any means other than those already employed in its treatment, and which may be said to be almost entirely empirical. Bloodletting, emetics, and purgatives have been employed by some; tonics and stimuli by others; and lastly, anodyncs and narcotics, all of which methods of treatment appear to have been more or less successful in one form of the disease, and of little or no avail in another. Stimulating lotions, warm fomentations, and friction appear to mitigate the local symptoms, and along with the general treatment, sometimes to arrest the further progress of the disease.

R. Carswell.

MUMPS. See Parotitis.

[MYELITIS. See Spinal Marrow, Diseases of the. It has been proposed by Dr. Marshall Hall, to call inflammation of the membranes of the brain *meningitis;* that of the substance or neurine of the brain *myelitis.*]

NARCOTICS, (from *νάρκη, stupor,*) syn. *hypnotica.*—These are medicines which in small or moderate doses produce temporary excitement succeeded by depression, which is generally followed by sleep. This definition does not comprehend the anodyne power strikingly displayed by many narcotics; because, although it is undeniable that many of them are capable of alleviating pain, yet, as this is not a general property of narcotics, it cannot correctly enter into a definition of the class.

Narcotics are commonly confounded with sedatives, but there are sufficient reasons for separating these two classes. In the first place *narcotics* operate as diffusible excitants, and by a proper regulation of the dose, and its administration at short intervals, their exciting influence only is obtained; in the second place, the depression or collapse which follows the administration of the full dose of a narcotic is the result of the previous excitement; and although this is not in the direct ratio of the degree of excitement, yet, if the excitant effect be considerable, and raised to its acmé, the succeeding collapse is proportionate. On the other hand, *sedatives* immediately depress the vital energies by a peculiar action upon the nervous centres, without causing previous excitement; and, if the dose be sufficiently large, they destroy both mobility and sensibility. Such are the distinctions between the effects of the administration of narcotics and sedatives,—distinctions undoubtedly sufficient to authorize the separation of these classes of medicinal agents.

The first effect of a moderate dose of any narcotic is an augmentation of the action of the heart and arteries, followed by an elevation of the heat of the whole body, and a slight sensation of fulness in the head. These symptoms are accompanied with an unusual exhilaration of spirits and aptitude for exertion; effects which, however, in a little time subside, and are followed by languor and drowsiness, gradually terminating in perfect sleep. The augmented arterial action is succeeded by a small, feeble, and irregular state of the pulse; the temperature of the body is lowered; and the respiration, which in the first instance was accelerated in the ratio of the augmented vascular action,

falls below the natural standard; an imperfect decarbonization consequently is effected in the pulmonary circulation; so that the blood transmitted to the brain being inadequate for due excitement, the whole system necessarily languishes. The function of the skin is, however, increased, and passive diaphoresis occurs, accompanied by itching and the dilatation of all the erectile tissues; finally, the glandular excretions are diminished, the mouth feels dry, and both the bile and the urine are evidently defective. The influence on the stomach varies according to the state of the organ; if the narcotic be taken into an empty stomach, it diminishes the desire for food; if swallowed at the time of taking food, the organ is enervated, and chymification suspended; if a short time after a meal, the process of digestion is arrested; and if vomiting be excited an hour or two afterwards, the food is ejected in the state in which it was swallowed. The same effects follow the introduction of a narcotic into the rectum: the intestines, besides, frequently lose their ordinary contractility, and costiveness ensues. This, however, is the result of a moderate dose of only some narcotics; others rather increase than diminish the peristaltic motion of the intestinal canal.* After awaking from the sleep induced by a narcotic, the individual frequently experiences slight headach, some degree of nausea, languor, and a more than usual susceptibility of impression, with tremours of the hands, which continue until some excitant, such as coffee or a glass of wine and water, be swallowed. By degrees these symptoms subside, and the system remains in its accustomed state, unless the dose of the narcotic have been more than can be termed moderate, in which case headach, sometimes vertigo and confusion of ideas supervene and continue for several hours; whilst anorexia, constipation, and a scanty urinary discharge are experienced for a considerable time, and the individual is left weak and uncomfortable.

If the dose of the narcotic substance be so large as to prove poisonous, headach, vertigo, imperfection of vision, and stupor, are experienced, without any previous apparent excitement; the person soon becomes motionless and insensible to external impressions; he breathes slowly; and for some time the expression of the countenance denotes only sound and deep repose. By degrees the features change, and acquire a ghastly character; the breathing, under the influence of some narcotics, is stertorous, as in apoplexy, under that of others it is soft and natural; the pulse becomes irregular, sinks, and at length is almost imperceptible; the muscles relax, the jaw falls, and death rapidly closes the scene. Many of the symptoms following the administration of such large doses of narcotics resemble, in some respects, those attending *apoplexy*; in others, those of *epilepsy*; and occasionally those of *hypertrophy* of the brain; but in every case the distinction is apparent, when the circumstances preceding and attending the attack are duly investigated. Thus, in apoplexy there are generally premonitory indications of the threatened attack; and when the sopor has commenced, the patient cannot be roused to any consciousness, which is not the case in narcotic poisoning. The same kind of sopor attends epilepsy; it terminates suddenly, and the attack of the paroxysm is abrupt. Cerebral hypertrophy is a slowly progressing chronic affection.

The influence of narcotics is modified by a series of circumstances; for example, by the nature of the narcotic, the extent of the dose, the time of the day at which it is administered, the combination in which it is given, the state of health of the individual, habits of life, age, sex, and temperament; climate, and idiosyncrasy. Before entering into the consideration of these, let us examine, briefly, the questions—do the effects of narcotics result from their direct influence on the nervous system? or is it secondary to their introduction into the circulation? These are points which have been long and strenuously agitated, and on which the most opposite opinions are maintained. There is no doubt that narcotics are in many instances received into the circulation, and that they are most active; indeed, so much so as to produce almost immediate death, when they are directly conveyed into it; as, for instance, by injection into the veins: yet even in this case their influence may be propagated by nervous communication, as we are led to conclude from the experiments of Messrs. Morgan and Addison, (An Essay on the Operation of Poisonous Agents on the Human Body: London, 1829,) who discovered that they produce in the sentient extremities of the nerves on the inner coats of the blood-vessels a peculiar impression which is conveyed to the brain along these nerves. This is also demonstrated by the rapid effects on every part of the system which follow their administration by the mouth; often in a space of time too short to be the result of absorption. It is also well known that, when the dose has been so large as to be suddenly followed by fatal effects, the whole quantity of the narcotic administered has been found in the stomach. Some striking objections, it is true, have been made to the conclusions drawn from the experiments of Mr. Morgan and Dr. Addison; but the explanation of the manner in which the effects of narcotics are diffused over the body does not rest on their experiments; the nature of the nervous system enables us to comprehend readily the manner in which this communication of impression is effected.

The primary action of narcotics is not confined to the nerves of the stomach; for if any narcotic, opium, or atropia, (the active principle of belladonna,) or daturia, (the active principle of stramonium,) for example, be applied to the surface of the body, the same results follow, although in a diminished degree, as display themselves, when they are taken into the stomach. If the application be made to an entire membranous surface, the energy of the narcotic influence is not in the ratio of the absorbing power of the surface; and if it be injected into the thorax, between the lungs

* These effects of narcotics on the alimentary canal are greatly modified by disease. In subacute inflammation, or a highly irritable state of the mucous membrane, vomiting is not unfrequently induced; in a relaxed condition of that membrane, the atony is augmented, and indigestion and constipation confirmed; in cancerous ulceration of the stomach, instead of allaying pain, narcotics cause pain, and excite vomiting and rigors, and the brain becomes powerfully affected. In irritable states of the intestinal canal, however, especially when spasm is present, they allay griping, resolve spasm, and produce an anodyne and salutary effect.

and the ribs, the action is more energetic than when the narcotic is taken into the stomach. The absorption, however, of narcotics cannot be doubted; and when a narcotic substance is applied to a wound, it is probable that in this case it operates chiefly by its absorption into the blood;* but although its influence can be impeded by a ligature on the blood-vessels, yet its operation does not essentially depend on its introduction into the circulation. When it is injected into the veins, the animal, as has been already stated, instantly expires, and this without convulsions. In this experiment all the muscles of the body are rapidly deprived of their contractility; and, therefore, the action both of the heart and of the respiratory muscles ceasing, death must necessarily follow. If these remarks be correct, it is evident that narcotics operate on the *brain* and the *spinal column* by entering the circulation when they are taken in moderate doses; but when they are swallowed in quantities sufficient to prove rapidly fatal, this effect is the consequence of their immediate influence on the nervous system; and when they are taken into the circulation, their effects may be still referred to the direct impression which they make on the nervous system. The nerves most particularly affected by narcotics are the respiratory; for when artificial respiration is maintained for some time in an animal poisoned by a narcotic, the animal recovers.

A question naturally suggests itself—how do narcotics produce sleep? Much difficulty attends the solution of this question; but some approach towards it may be attained by keeping in view the state of the vital functions during sleep. In this condition of the body, the pulse beats more slowly than when the person is awake; the temperature of the body is diminished, the perspiration is decreased, and nearly all the secretions are suppressed. Now on whatever principle narcotics act, if their primary stimulant influence is followed by a diminution of the force and frequency of the circulation, and at the same time of the respiratory effort, the change of the venous into arterial blood must be necessarily impeded; and this alone, by weakening the energy of the brain, will cause sleep. Such, at least, is the theory which the writer of this article is inclined to offer. It may be objected that this explanation applies equally to all the stimulants; and such is really the case, as all transitory stimulants, according to the extent of the dose, operate like narcotics, and produce sleep. But there is still something connected with the anodyne influence of narcotics which we cannot readily explain, and which requires a more intimate acquaintance with the nervous system than we at present possess.

Circumstances which modify the action of Narcotics.

1. *Nature of the Narcotic.*—The general effects which have been described as resulting from the administration of a narcotic are those which opium produces. When acetate of morphia is substituted for opium, and a full dose is administered, another symptom displays itself: the patient, when in the horizontal posture, is attacked with shocks, as if electrified; the head is thrown backwards as in opisthotonos; and a paralytic condition of the bladder of urine supervenes, although there is no diminution of the secreting powers of the kidney. If the muriate of morphia be employed, little or no excitant effect is perceived, whilst the sedative influence is most obvious. Belladonna, hyoscyamus, and aconitum, are more directly anodyne, and even in small doses affect the sight more than any other narcotics; and when the two former are overdosed, and delirium succeeds, it more resembles the delirium of intoxication than that of narcotism. Irregularity of arterial action characterizes the operation of conium, the pulse being in some instances sunk, in others increased to one hundred or more during the whole time of administering the medicine. When over-dosed, the breathing is more oppressed, and the thorax more constricted than with any other narcotic, while the countenance assumes the aspect of that of a man who has been strangled. Digitalis accumulates in the system, and veratria (colchicum *autumnale*) operates chiefly on the duodenum, producing copious bilious stools; thus lessening febrile action, and allaying pain.

2. *Extent of the dose.*—The influence of small and large doses of narcotics has been stated; and in many morbid states of the habit they may be employed to produce either stimulant or sedative effects. Unless the dose be large enough to diminish sensibility, they cannot be administered with the view of procuring sleep. In cases of inflammation, after the use of the lancet, large doses of narcotics are generally productive of the most salutary effects; on the contrary, small doses are likely not only to counteract the benefit derived from the bleeding, by their stimulant influence, but, if their administration be repeated, to augment the evil. In all painful and spasmodic affections, the extent of the dose is to be limited only by its effects: thus in tetanus, one hundred drops of the tincture of opium have been administered every hour with the best effect; and the writer of this article, in cases of gall-stones and renal calculi, has given upwards of eight hundred drops of the officinal tincture of opium in less than twelve hours, without any effect but that of relieving pain and aiding the passage of the concretions: indeed, narcotics may be persevered in to any extent, as long as they display no determinate action on the habit. The dose in such cases requires to be progressively augmented; if no relief be afforded in three or four hours, it should be doubled, and so on until the benefit anticipated be obtained.

3. *Period of the day.*—When narcotics are administered in the morning, especially on an empty stomach, considerable excitement is induced, and the anodyne and hypnotic effects of the medicine seldom follow; on the contrary, if the same dose be given in the evening, little excitement supervenes, and the desire of sleep is so great that it is impossible to avert it.

4. *Combinations.*—Narcotics, when uncombined with other substances, produce the effects already described; but in combination with many different substances, their operation is greatly modified. Thus, in conjunction with tonics, instead of checking chymification, they promote the appetite and favour the digestive function; aromatics oppose their sedative influence, and delay

* M. Lesieur of Paris applies narcotics to blistered surfaces in preference to their internal administration.

their soporific effect; combined with diaphoretics, whilst the function of the skin is augmented, their influence on the brain is diminished. Acids promote their powers; while alkalies, by decomposing their active principles, and withdrawing the acids which render their alkaloids soluble, diminish them, and in many instances render the narcotic inert. We shall notice these effects of combination in describing the individual narcotics.

5. *Habit.*—Narcotics lose their influence when they have been taken daily for a considerable time; and doses have been swallowed under such circumstances which would at first have proved fatal. This effect of habit in modifying the action of narcotics has not been satisfactorily explained, although M. Charvet has attempted it in reference to opium. He assumes that the state of congestion of the brain is admitted as the effect of an over-dose of opium, and supposes that the frequent use of the drug renders this less considerable; or that the brain, accustomed gradually to the flow of blood and resulting compression, at length is enabled to bear it with impunity, in the same manner as when a serous effusion gradually occurs, or a tumour is slowly developed in the brain. (*Charvet* de l'Action comparée de l'Opium.) There is much ingenuity in this explanation; but the power of habit in modifying and resisting the influence of some narcotics is not extended to all; and, indeed, there is little similarity of action among narcotics: each has its own specific or peculiar action on the nervous system, a circumstance which enables the physician to accommodate narcotics to the constitutions of his patient. This is peculiarly striking with respect to the anodyne and hypnotic properties of narcotics: after the failure of one, the administration of another will fulfil the intention of the subscriber, whether it is intended to allay pain or procure sleep. It is an equally curious fact, and one of practical importance, that this force of custom in reference to one narcotic does not render the system less susceptible of the impression of moderate doses of another: the opium-eater, accustomed to take a drachm of his favourite narcotic daily, may be lulled to rest by a few grains of henbane or conium.

It is unnecessary to mention many instances in proof of the extent to which the doses of narcotics may be carried with impunity by those who have long accustomed themselves to their use. Russell, in his History of Aleppo, states that Mustapha Shatar, an opium-eater at Smyrna, took daily three drachms of the drug, and felt a necessity for increasing the dose. Dhere, a French author, mentions the case of an officer of the same nation who took a drachm of pure opium daily, and appeared in good health, although an alvine evacuation was procured once only in eight days, sometimes once only in fifteen days. But no work affords so much curious information on this part of our subject, and so displays the extent to which the doses of some narcotics may be carried, as the Confessions of an English Opium-eater. It is, nevertheless, true that the habitual use of narcotics wears out the powers of life, and leads on to premature old age. The symptoms which follow the use of opium, for example, thus indulged in, closely resemble those brought on by excess in venery; marasmus and decrepitude supervene; the mind equally suffers; and the wretched individual sinks into the grave a deformed and slavering idiot.

6. *Age.*—The younger the person, the more energetic is the action of narcotics on the system; they even prove injurious to the fœtus, when they are prescribed to relieve cramps, or allay inquietude in the mother; thence the necessity of caution in administering them to infants, in whom both convulsions and epilepsy have followed their use.

7. *Sex.*—Narcotics exert a more powerful influence on women than on men, a circumstance which might, *à priori*, be expected from the greater susceptibility of the female constitution. To pregnant females, also, narcotics must be administered with the greatest caution, as in this condition of the female habit a state of the cerebral function frequently occurs, which is augmented by the operation of narcotics, and might be productive of dangerous consequences.

8. *Temperament.*—There is but one opinion respecting the power of temperament in modifying the operation of narcotics. In the *sanguine* temperament the nervous system is highly sensitive, and susceptible of every impression, and the body predisposed to inflammatory action. There can be no doubt that narcotics will produce a more powerful impression on such a temperament than on the opposite or *melancholic*. In those persons, for example, who are easily affected by wine, and in whom inebriety is quickly produced, a small dose of opium causes powerful cerebral excitement; thence the maxim of Tralles, "Illi vero omnes qui vinum non bene ferunt vix bene ferent opium." On the same account, a condition of habit likely to favour cerebral congestion is much more likely to be powerfully influenced by narcotics than a spare habit—a fact which ought never to be lost sight of in practice.

9. *Climate.*—The action of narcotics is powerfully modified by climate. The same dose of a narcotic which produces only beneficial effects in Great Britain, has been found to operate too powerfully in Italy; some attention is, therefore, necessary, in prescribing narcotics, to accommodate the doses to the nature of the climate in which the physician is practising. On the same principles, season modifies their action, and smaller doses are required in summer than in winter. These observations seem, nevertheless, at variance with the result of temperature on opium, the brain being less affected when the patient is kept in a temperature which excites perspiration than in one which is cooler. M. Hecquet (Vide Charvet de l'Action de l'Opium, p. 58) explains this influence of temperature in the case of opium, by saying, that as heat favours the flow of sweat, the opium is carried out of the habit with it, and is thus prevented from affecting the brain. Charvet supposes that, as copious sweating diminishes the mass of the circulating fluids, and renders the cerebral compression less powerful, the sweating may be regarded as a favourable crisis which guards the brain from over-compression. Both opinions are hypothetical; and it is more likely to depend on the greater irritability of the habit in warm climates than in cold, and the consequent greater susceptibility of impression.

10. *Idiosyncrasy* is more likely to influence the action of narcotics than any other classes of medicines. In some individuals opium, for example, even in moderate doses, produces restlessness, delirium, and convulsions; in others miliary eruptions; and in some its soporific effects are never experienced until the day following that on which it is taken.

With regard to the employment of narcotics, were it consistent with our plan to enter into the history of this class of remedial agents, we should remark on the very early period in which mankind appear to have been acquainted with their effects. In every nation, and among every people, from the southern islander, who chews the kava, and with his own saliva manufactures the intoxicating bowl, to the polished European, who indulges in the fermented juice of the grape, all seek in narcotics, not only oblivion from pain, but a balm for the cares and sorrows of life—"ducunt sollicitæ jucunda oblivia vitæ."

When narcotics are taken in over-doses, they produce the effects which have been already described: post-mortem examinations of the body display the brain gorged with blood; and not unfrequently water is found in the ventricles. In cases of supposed poisoning by narcotics, however, care must be taken not to confound the symptoms with those arising from diseases; in particular, apoplexy and epilepsy, which, as has been already stated, display symptoms closely resembling some of those attending poison by narcotics.

With regard to the *practical employment* of narcotics, it is obvious that they ought not to be prescribed in cases in which their primary excitement would prove hurtful, unless the dose be large enough to induce symptoms of diminished sensibility and lessened action without any previous excitement; and experience teaches us that this is the result when a large dose of a narcotic is administered, particularly when it is taken immediately after a copious abstraction of blood; but if the dose be small, the opposite effect follows, proving that the patient may be either greatly benefited or materially injured by the extent of the dose of the narcotic, which it may be thought proper to prescribe. Thus if, in a case of pleurisy, the pulse be hard, quick, and forcible, and the pain of the side so acute as almost to prevent even a half inspiration, if a free bleeding be resorted to, two grains of opium, in conjunction with the same quantity of calomel, and a quarter of a grain of tartar emetic, may be prescribed with the prospect of much benefit; but if half a grain only were ordered, not only would no advantage accrue from the narcotic, but the stimulant effect alone being obtained, the benefit of the bleeding would be counteracted rather than maintained, and the repetition of the dose would only increase the evil. In this respect the action of narcotics does not differ from that of direct stimulants. In all cases, therefore, of increased excitement, when pain or restlessness demands the administration of a narcotic, the dose should be sufficiently large to obtain at once its anodyne effect, without the primary stage of excitement.

[Narcotics, in full doses, are precious sedatives; and, as such, may be employed in many phlegmasiæ, even from the very onset of the disease. They are remedies that have been but little understood, and the idea, that they are, under all circumstances, stimulants, has occasioned them to be discarded in diseases in which they would have afforded signal relief.]

The stimulant influence of narcotics in small doses is frequently taken advantage of in the treatment of fevers of a low or typhoid state. The tincture of opium, for example, given in doses of ten minims at short intervals, augments the strength of the pulse, rouses the vigour of the system, and sometimes supports the strength.

Narcotics may be arranged under two distinct heads, namely, *direct narcotics* and *indirect narcotics*. Under the former may be placed all those substances which produce their effects by a direct impression on the nervous system, without necessarily entering the circulation: under the latter those which enter the blood before acting upon the nervous system; for even when they enter the circulation their influence is still exerted upon the nerves. The continental physiologists have made many experiments to ascertain the manner in which narcotics operate, and have deduced this inference, that the narcotic must be transmitted to the brain through the blood before it acts; but it is more probable that in full doses direct narcotics operate by an immediate impression on the sentient extremities of the nerves.

The number of narcotics is considerable, but the most valuable are *opium*, and the salts of *morphia, henbane, conium, belladonna, lactucarium*, and *camphor*. It is incompatible with the plan of this work to enter upon the natural history, chemical properties, and pharmaceutical preparations of these substances; it is to their importance and employment as remedial agents that we have to direct the attention of our readers.

Like all other narcotics, *opium* exerts a primary stimulant effect on the living system, whether it be introduced into the stomach or into the rectum, or injected into a vein, or applied to wounds or ulcers, or rubbed on the surface of the body. When taken into the stomach in a solid form, it undergoes partial digestion; this process separating, in a great degree, the active principles, the *meconate of morphia*, the *narceine* and *narcotina:* thence the salts of opium act more rapidly than the entire opium.* During the continuance of the

* The components of opium are—

1. *A volatile oil*, on which the odour of the drug depends, but existing in such small quantity that it can scarcely be procured in a separate form. Water distilled from opium contains it, and is productive of slight cephalagia when snuffed up the nostrils, but it displays no other narcotic property.
2. *Gum*, including *bassorine*.
3. *Extractive*, partly simple, partly unusually oxydized.
4. *Resin*, with which the colouring matter is closely combined; and this in conjunction with the volatile oil may be the source of the stimulant property of the drug.
5. *Caoutchouc*.
6. *Narceine*, a new principle lately discovered by M. Pelletier; it is crystallizable, is soluble in water and alcohol; insoluble in ether; and has a bitter styptic taste. Its action on the animal economy is unknown.
7. *Meconine*, another new principle, also discovered by the same able chemist; crystallizable; little soluble in cold water, but very soluble in hot water.
8. *Morphia*, in combination with meconic acid as a bimeconate.

stimulant effect of opium and its salts, the cuticular secretion is augmented, but some of the other secretions are diminished: the urine, for instance, is scanty and high-coloured; and after this state is over, the pale, clay-coloured aspect of the alvine discharges indicates a greatly diminished excretion of bile. The stimulant effects of a moderate dose of opium are soon dissipated; and the administration of a much smaller dose, after a short interval, produces more intense effects than the first dose, although the reverse of this follows the continued use of the drug. If the opium be taken on an empty stomach, the excitement is greater than when it is swallowed soon after a meal: in the first case the pulse remains small, although hard, and symptoms of cerebral congestion rarely appear; on the contrary, symptoms of congestion appear sooner, and are more obvious, if the same dose be taken just after a meal. From experiments made by Dr. Crump (An Inquiry into the Nature and Properties of Opium, &c. 8vo. 1793) and others, it is evident that the exciting influence of opium differs little from that of other stimulants; but the sleep which follows the excitement of wine and ordinary stimulants differs from that procured by the influence of opium; nor do these possess the power of opium in relieving pain: it is therefore fair to conclude that, in its sedative influence, opium is distinguished from all other stimulants.

Although it is probable that the effects of opium on the living system are attributable to its direct influence on the nervous energy, yet it must be admitted that there are facts which tend to shake this opinion; and one of the strongest is related by M. Barbier, from which it appears that an infant was affected by the milk of its mother, who had taken a large dose of the wine of opium. But as alcohol is undoubtedly taken up by the absorbents, it is probable that the absorption of the opium in this case is to be attributed to the vehicle; and it is only by admitting the direct influence of opium on the sentient extremities of nerves, that we can explain the relief obtained in instances of severe pain.

Many circumstances, as has been already stated with respect to narcotics in general, modify the operation of opium on the living system. The first of these is age: opium operates with most energy on the young, consequently the greatest caution is requisite in administering it to infants, in whom it often excites convulsions; even in the state of syrup of poppies, too often administered to infants by lazy nurses. A low irritative febrile state, depending on the continued cerebral excitement produced by the medicine, gradually brings on marasmus, and undermines the powers of the constitution. The influence of sex is less than that of age; but still experience has proved that women are more easily affected by opiates than men.

9. *Narcotina*, which has been supposed to be the stimulant principle of the medicine.
10. *Sulphates of lime and of potass.*
11. *A brown acid.*
12. *Lignine* or *woody fibre.*

[The most recent researches have shown, that it has at least the following constituents: morphia, narcotin, codeia, narcein, meconin, thebain or paramorphia, pseudomorphia, meconic acid, brown acid extractive, sulphuric acid, resin, fat oil, gummy matter, caoutchouc, albumen, odorous principle and lignin.—Pereira, *Mat. Med.* Amer. ed. ii. 716, Philad. 1843.]

The effect of custom in modifying the influence of opium on the system is so well known as scarcely to require it to be noticed. The extent of the dose to which it may be carried by those in the habit of taking it daily is wonderful, but still larger doses may be given to allay pain and spasm. Dr. Chapman mentions that, in a case of cancer in utero, he has given the tincture to the extent of three pints in twenty-four hours, without any other effect than that of relieving pain.

The combination of other substances with opium greatly modifies its action on the system. When combined with antimonials, not only are its diaphoretic powers increased, but it is rendered less likely to impede the other secretions. With acids, half the usual dose will produce the effects of a full dose, an effect evidently resulting from the production of a more soluble salt, the acetate, the citrate, the sulphate or the muriate of morphia, according to the acid employed. When we order it with the view of procuring sleep, we should not combine aromatics with opium, as these increase its stimulant, but lessen its sedative influence.

Morphia, the active principle of opium, exists, as we have already said, as a bimeconate in opium; but when it is separated from the other components of the opium, it is generally administered in combination with acetic, or muriatic, or sulphuric acid, as an acetate, muriate, or a sulphate.* Any one of these salts, when administered in doses of a quarter of a grain repeated at short intervals, causes a sensation of fulness in the head, some obscurity of sight, tingling of the ears, cephalalgia, vertigo, and a tendency to sighing and sleep. The pupils are sometimes dilated, at other times contracted, and sometimes are not at all affected; the pulse is not much accelerated: occasionally there is a sensation of itching all over the skin, frequently nausea, and a difficulty in passing urine. In large doses the cerebral excitement is alarming. From some observations made by M. Bailly, in the Hôpital de la Pitié in Paris, it appears that full doses of acetate of morphia sometimes excited shocks like those of electricity, when the person was lying in the horizontal position: the muscles lost much of their contractility, and the sight was greatly impaired. As, in these cases, the pulse was diminished both in force and frequency, Bailly was led to infer that morphia acts as a sedative on the heart, and as a stimulant on the nervous system; it would, perhaps, be nearer the truth to say that it acts as a stimulant on the nerves of sensation, and as a sedative on those of motion. It seldom increases the temperature, although sometimes its salts greatly aug-

* Acetate of morphia is thus prepared: a specific quantity of morphia dissolved in alcohol is saturated, accurately, with pure acetic acid; and the solution evaporated with the gentle heat of a vapour-bath to dryness. The sulphate is prepared in a similar manner, care being taken to employ the acid in a dilute state. The muriate may be readily prepared by precipitating an aqueous solution of opium by means of muriate of baryta; a meconate of baryta, which is insoluble and falls to the bottom of the fluid, and a muriate of morphia which is soluble, are obtained. By evaporation of the fluid, the muriate crystallizes in tussocks consisting of aggregations of acicular crystals; by pressing these between colourless blotting-paper, the narcotina is separated, and the muriate obtained in an impure crystalline state. It is purified by repeated solutions and recrystallizations. [For the different modes of preparing morphia and its salts, see Pereira, *Op. cit.*]

ment the exhalant function of the skin. In overdoses, whilst the upper part of the body is bathed in a viscid sweat, the lower extremities are cold; there are violent tremours; the body acquires a livid hue; the face has a pinched and cadaverous aspect; and death ensues without convulsions.

The *black drop* has all the progerties of acetate of morphia in combination with aromatics.*

From what has been said, it is evident that in prescribing opium we must always keep in view both its stimulant and its sedative influence.

[*Codeia.* The experience of different observers, as to the effect of codeia on the economy, has been discordant. Magendie (*Formulaire pour a préparations, &c., de plusieurs nouveaux medicamens, &c.,*) states, that it causes sleep, and, in large doses, stupor. He considers one grain to be equivalent to half a grain of morphia. A syrup, each ounce containing two grains of codeia, has been given in hooping-cough, and in other diseases in which opium has been found useful; and with Dr. Miranda (*Journal de Pharmacie*, xxiv. 145, Paris, 1838,) it has proved serviceable in what he terms "powerful nervous irritations of the mucous membrane of the stomach." It would not seem, however, to possess any virtues not contained in morphia, whilst its cost is excessive. (For the mode of preparing it, see the writer's *New Remedies*, 4th edit. Philad. 1843.)

Narcotin. The views in regard to the precise properties of narcotin are also contradictory; and owing to the uncertainty in regard to its action, it is but little employed. It would seem that the exciting properties of opium do not belong to it exclusively, as has been supposed by some, inasmuch as there are persons who are as disagreeably affected by morphia alone as they are by opium, which contains both morphia and narcotin. Recently narcotin has been employed as an antiperiodic. See TONICS.

The other constituents of opium are not of much, if any, therapeutical interest. Narcein, meconin, pseudomorphia, and meconic acid, appear to be inert; and, according to Magendie (*Op. cit.*), thebain or paramorphia, when injected into the jugular vein, or placed in the pleura of an animal, causes tetanus and death in a few minutes.]

Practical employment of Opium.—In *intermittent fevers* the employment of opium is as old as the time of Galen. The best time for administering it is an hour before the expected paroxysm, as at this time it weakens the force of the attack, and sometimes prevents its accession; a result probably due to its stimulant property, whilst, at the same time, its sedative quality allays the morbid irritability connected with ague. The dose should be large; for example, from forty to sixty minims of the tincture. When given during the hot stage, as Lind recommended, it renders that stage shorter and milder, lengthens the intermission, and greatly promotes the influence of bark or the sulphate of quinia in curing the disease. In combination with calomel, in doses of a grain of each, it also enhances the sanative powers of tonics, in cases which resist them when given alone. But if opium fail to check the accession, it should not be given in the succeeding paroxysms, as the repetition of it in such a case only tends to induce debility.

In *continued fevers* the use of opium is more questionable than in intermittents. It should not be ordered if the temperature of the surface be much greater than natural, unless there be a tendency to perspiration, which it accelerates, and thence proves beneficial. If pain and watchfulness demand its use, the dose should be large, and it ought to be united with calomel and tartar-emetic, a combination which greatly lessens its stimulant properties. In this combination and with James's powder, Dr. Currie employed it with great advantage after the cold affusion. In the advanced stages of typhus, opium is useful as a general stimulant, in doses of from six to ten minims of the tincture, or from three to six minims of the black drop, in combination with camphor and other cordials. When, in the early stage of continued fever, the pulse is full and hard, the heat of the surface greater than natural, the thirst considerable, and there is much headach, the use of opium is not admissible. Even in the sinking stage of this disease, wine is a better and more permanent stimulus. In typhus, the symptoms that chiefly indicate the use of opium are low muttering delirium, watchfulness without increased heat of skin, diarrhœa, and subsultus tendinum: the dose should be small, frequently repeated, and cool air freely admitted to the chamber of the patient. If the delirium, however, be accompanied with flushing of the face, impatience of light, and throbbing of the temples, it must not be administered.

If opium be prescribed to counteract watchfulness, it should be recollected that this may arise from very opposite causes. When it is accompanied with great heat of surface, restlessness, tossing about in the bed, and determination of blood to the brain, it proves deleterious; if none of these symptoms are obvious, then opium is the best means for overcoming such a state of watchfulness. It should be given in full doses, in a solid state combined with calomel, at the usual time of rest; and during its operation the scalp should be kept cool by enveloping the head in a cloth wet with a cold lotion. In low delirium it may be given at the same time as ammonia; but if, as sometimes occurs, it increase the delirium when it is taken into the stomach, then it may be applied by aid of friction dissolved in oil.

The best preparations of opium are the *tincture* of the pharmacopœias, the *black drop*, the *liquid laudanum of Sydenham*, the *solution of the muriate of morphia*, and the *acetate of morphia*.

With regard to the extent of the dose, it should be held, as a general rule, that double that which

* The black drop is prepared by rubbing half a pound of opium, reduced to powder, with four pounds of verjuice, one ounce and a half of nutmegs, half an ounce of saffron, and three ounces of sugar. These ingredients are fermented with yeast for six days; the fluid is then to be decanted, filtered, and inspissated in the air to the consistence of syrup. The strength of the black drop compared with that of tincture of opium is as three to one. An excellent preparation, which owes its activity to the citrate of morphia, is ordered to be thus prepared in the Brunswick Pharmacopœia. "Dissolve four ounces of opium in forty-eight ounces of water, acidulated with six ounces of lemon-juice; filter and evaporate to the consistence of an extract in a water-bath." The citric acid, in this case, decomposes the bimeconate of morphia, and affords a more soluble salt, the citrate of morphia, which is conjoined with the gum and extractive of the opium.

is required to produce sleep in a state of health should be administered in disease; if acetate of morphia be preferred to any of the other preparations, when narcotic not hypnotic effects are desired, the following formula will be found useful:

℞ Morphiæ, gr. ii.
Acidi acetici, *m* ii.
Misturæ amygd. amaræ, f.℥vi.
Syr. tolutani, f.℥i.

Tere morphiam cum acido et syrupo, dein adde misturam. Sumatur quarta pars sextâ quâque horâ.

In the *phlegmasiæ*, notwithstanding the general rule that opium should not be administered during the presence of active inflammation, until the system have been relieved by bleeding, there are cases in which it proves highly useful; as for instance, when the inflammatory action is of a passive kind, as in malignant ulcerated sore throat, and in chronic rheumatism. But even when it is of the opposite description, as in pleurisy, if venesection be freely employed, nothing is so likely to subdue permanently the inflammatory action as large doses of opium in combination with calomel and tartar-emetic. When the inflammation is in the substance of the lungs, as soon as dyspnœa is relieved, and the symptoms are reduced to cough and restlessness, opium may be given with the hope of the greatest advantage: indeed, all acute inflammatory affections of the chest may be benefited by opium thus preceded by antiphlogistic measures. In peripneumonia notha, both in that variety which constitutes the catarrhus suffocativus of old age, and that in which there is a congestion of blood in the pulmonary vessels, opium is useful. In the first place it forms an active and useful ingredient in stimulant expectorant mixtures, with ammoniacum and squill; and in the second, after the congestion is partially relieved, the liberal administration of opium in combination with demulcents is productive of much benefit. It may be said that this opinion is at variance with the common idea that opium retards expectoration; but in reply to this objection, let us examine what the state of the chest is in pneumonia. We find that the pain is aggravated by a full inspiration, and that, in order to obtain this, the patient must be nearly in the erect posture. Now, under this state the necessary change cannot be effected on the blood; and in the irritable state of the bronchial membrane the secretion of its natural mucus is hurried, and the sputa consequently thin and acrid. In this condition, opium, acting through the pneumogastric nerves, allays pain, and enabling the patient to take a fuller and more perfect inspiration, it is easy to comprehend how a thicker and more slowly secreted mucus will be coughed up more easily than a thinner and more irritating matter. It is on this account that opium, instead of restraining, frequently promotes expectoration.

[In many of the phlegmasiæ, opium is a most valuable sedative, even from the first onset of the disease. In sero-enteritis, it was highly extolled by Armstrong, (*Lectures on the Morbid Anatomy, Nature and Treatment of Acute and Chronic Diseases*, Amer. edit. Philad. 1837,) especially when given after bleeding had been practised; and he was in the habit of saying, that if he himself were labouring under the disease, and were told that he must rest his hopes of recovery on the lancet singly, or on opium singly, he should be disposed to select the latter.

What Armstrong said of the use of opium in these cases has been extended to similar pathological conditions in other serous tissues and elsewhere; and many advantages have accrued from its employment, in some form of preparation, in cases in which, at one time, its use was unknown, or considered inappropriate. Dr. Christison, (*Edinb. Monthly Journ. of Med. Science*, Feb. 1841, p. 91,) has recently shown, that coryza, catarrh, influenza, and dysentery may be frequently cut short by a full dose of it; and that when conjoined with ipecacuanha, it has often the same effect on common sore-throat, catarrh and acute rheumatism. He also is a great advocate for the full employment of opium early in inflammations after a deep impression has been made by bloodletting.

The common remark, that opium is so well adapted for cases of pneumonia, bronchitis, &c. because it "diminishes the secretions," appears, as the writer has said elsewhere, (*General Therapeutics and Materia Medica*, i. 337: Philad. 1843,) a faulty method of explaining its action. The suppression of secretions is not a pathological condition; it is only the symptom of such a condition—and when it is stated, that the indication is "to restore the secretions," if the expression have any meaning at all, it can only convey the idea, that the pathological condition, which occasions their suppression, must be removed. Now, we know, that the first effect of the inflammation of a mucous membrane is a diminution of its natural secretion; and that, after the inflammation has continued for a time, an increase of the secretion takes place; but it is no longer of the normal character. It is a secretion effected by vessels labouring under inflammatory excitement. Two opposite effects, then, on the secretory function are produced by different stages of inflammation. Yet the indication in the two cases must obviously be identical. It must be—to remove the pathological condition of which these effects are symptomatic. A narcotic, in appropriate doses, is a sedative; it is, therefore, well adapted for allaying inflammatory excitement.

A knowledge of these properties would suggest the propriety of its employment in the diseased state of mucous membrane referred to above; and experience ought to show, as it daily does, that in the early period of inflammation of a mucous membrane it will, in sedative doses, "restore the secretions;" and at a later period, when the mucous secretions have become profuse and morbid, it will diminish them, by diminishing the inflammation that occasioned them. It is obviously, therefore, incorrect to lay down the broad law, that "opium diminishes the secretions," and that its use is improper whenever the indication is "to restore the secretions." Such an indication ought never to be imagined. It is unmeaning, and can only have been suggested in an ignorance of true pathology; and the writer is happy to find, that his views on this subject have met with the entire accordance of others who have investigated

the subject pathologically and practically. "The objection to the use of opium in the treatment of bronchitis, pneumonia, &c. on the ground that it diminishes the secretions," says a recent therapeutical writer, Dr. Spillan, (*A Manual of General Therapeutics*, &c. p. 155: Lond. 1841,) has been happily refuted by Dr. Dunglison."]

Opium is indisputably a most useful medicine combined with ipecacuanha, or camphor, or ammonia, as circumstances may require, in malignant peripneumony. In ophthalmia it is exhibited under the same restrictions as in pneumonia. If pain and irritation be excessive, it may be given even before bleeding has been resorted to, in which case it should be combined with calomel and tartar-emetic. Externally no application is more useful, after the active inflammation has been subdued by topical bloodletting. The old *solutio opii vinosa* is preferable to the vinum opii of the modern pharmacopœias, as it contains only half the quantity of opium and an aromatic. It acts partly by its stimulant, partly by its narcotic properties.

Opium has now almost supplanted the use of the lancet in acute rheumatism: it should be administered in full doses, immediately after active purging, in combination with colchicum. In the chronic form of the disease the opium may be combined with sulphate of quinia, or with infusion of menyanthes *trifoliata* acidulated with muriatic acid, which gives activity to the opium by forming a muriate of morphia.

In gout, even in that variety of the disease which is named retrocedent, opium is truly our sheet-anchor, and it must be given in full doses. In some cases it has been administered in doses of ten grains twice a day with advantage; and no consequent inconvenience is experienced if the dose be not too hastily lessened. In the acute form of the disease, opium is most useful when combined with colchicum. Something in this combination is due to the specific action of the colchicum on the gall-ducts. It has been supposed that the opium diminishes or impedes the biliary secretion, because the evacuations which follow a dose of opium are frequently pale; but this only indicates a diminished excretion. In the lower animals poisoned by opium the gall-bladder and ducts are turgid with bile, although very little had found its way into the duodenum. Now, as colchicum stimulates the gall-ducts, the combination of this remedy with opium removes the objection to its employment in gout, as far as regards the biliary secretion.

It is almost unnecessary to say that in cases of biliary calculi impacted in the gall-duct, or in nephritic inflammation arising from the irritation of renal calculi, either in the pelvis of the kidney or in the ureters, the best results are to be anticipated from the use of opium, particularly when the stomach is so irritable as to reject, by vomiting, every thing received into it. In this case, on account of the advantages to be expected from proximity of action, the opium is most beneficial when exhibited per anum, dissolved in oil. In suppression of urine, also, from calculi irritating the bladder of urine, or from stricture of the urethra, opium in combination with calomel is the medicine most to be depended on; and the same combination acts as a powerful anodyne in chordee, and the painful micturition of gonorrhœa. Neither large doses of opium alone, nor large doses of calomel, produce the effect of the combination of these medicines. Two grains of each may be administered in the form of a pill every second or third hour. The writer of this article, however, has sometimes found it better to order eight grains of calomel and two of opium, to be taken every eighth hour until relief was obtained.

Small-pox is the disease among the exanthemata in which opium is most decidedly indicated; and we are indebted for this fact to the sagacity of Sydenham. In the distinct form of the disease it is not required unless convulsions occur, or the eruptive fever be accompanied with much restlessness. Perhaps the practice of Sydenham, of administering opium every night in confluent small-pox, has been too indiscriminately followed. It is not required in the greater number of cases during the progress of the eruption, although it is occasionally useful for promoting the maturation of the pustules; and after the eruption it is indicated, under the same circumstances as in typhous fever, in conjunction with cinchona bark and wine. It is also useful in the secondary fever, if diarrhœa supervene; for notwithstanding the authority of Sydenham, purging at this time ought to be restrained to a certain extent. In measles, the employment of opium is contra-indicated in the commencement of the attack, but after the inflammatory symptoms are subdued, and the cough remains, then opium in combination with calomel and ipecacuanha will be found beneficial, and still more so if the diarrhœa, which to a certain extent is useful, proceed too far. In that form of the disease which is of a malignant nature, rubeola *maligna*, as the fever is of the typhoid type, opium is indicated, and may be given throughout the attack, under the same regulations as in typhous fever.

Much difference of opinion exists respecting the employment of opium in hemorrhages. When febrile symptoms exist, these should be subdued before opium is prescribed; when the hemorrhage is connected with much debility, laxity of the solids, and a thin state of the circulating mass, then opium in combination with astringents and tonics should be administered to allay the irritability which always accompanies this state. In hæmoptysis, when no inflammatory state of habit exists, when the bleeding is kept up by cough, and is accompanied with watchfulness, opium is likely to prove useful: in the opposite state, if much irritation exist, it should be combined with either digitalis, or acetate of lead, or hydrocyanic acid, and cold both topically and generally applied.

In phthisis pulmonalis opium is administered to allay cough, and to moderate diarrhœa when it is present. If the accession of the hectic paroxysm be well marked, it should be given at that period. It is usually administered at bed-time; but as it is apt to excite much perspiration, it is preferable to defer it until early in the morning, when the cough is most severe. The soluble salts of morphia, especially the acetate, are preferable to opium, as they do not excite perspiration in small doses. The following formula will be found very serviceable:

℞ Acidi acetici diluti (aceti dest.) f.℥iv.
Acetatis zinci solut. P. E. f.℥i.
Tinct. opii *m.* xii.
Decocti lichenis Islandici f.℥xi. M.
Haustus quintâ quâque horâ sumendus.

In no disease has opium been more frequently employed than in dysentery; but there is much difference of opinion as to the propriety of this practice. If pains and tenesmus continue after the bowels have been freely evacuated, opium, combined with ipecacuanha, will be found useful; but during its use the bowels should be freely evacuated once at least in twenty-four hours. When the tenesmus is very urgent, the opium should be exhibited, in conjunction with demulcents, in the form of enema; and towards the close of the attack, when the disease may be regarded as having passed into diarrhœa, opium is the proper remedy. In bilious colic, and some other affections of the bowels in which pain and spasm arise from the action of highly irritating matters on the coats of the intestines, and in which purgatives do not act freely, experience has proved the propriety of combining opium with purgatives. In conjunction with calomel in large doses, it allays the irritation both of the stomach and the intestines, removes spasm, and consequently aids the operation of the purgatives. Indeed, in almost all spasmodic affections opium is the remedy to be relied upon, whether the spasm arise from the action of some irritating substance on the moving fibre, or from irritation kept up by debility: the cure consists in removing the irritating cause, and diminishing the susceptibility of the muscular fibre by restoring its tone. The term "almost all" is employed, because in some spasmodic affections opium seems to produce deleterious effects: thus in hay asthma it augments fever, headach, and the wheezing and suffocative tightness across the chest, which characterizes that singular disease. To answer both the above intentions opium is admirably adapted, when it is given in combination with sulphate of quinia and other tonics.

In idiopathic tetanus, opium is a remedy of great power; in traumatic tetanus it is of less value even in the largest doses. In the idiopathic form of the disease, opium should be early administered, as the progress of the attack is rapid, and the power of deglutition may be soon lost. The extent to which the remedy may be given is limited only by its effects; many ounces of the tincture have been taken before its effects have been felt. Its stimulant influence quickly disappears, on which account, even after the spasms are controlled by it, the use of it should not be discontinued for some time. A case is recorded in which fifteen hundred grains of solid opium were taken in the course of seventeen days; and another in which twenty fluidounces of the officinal tincture were swallowed in twenty-four hours: both cases recovered. In general, the following rules should regulate the progressive increase of the dose, and its repetition. If the spasms be moderate, ten or twelve minims may be given every hour; but if no relief be afforded in three or four hours, the dose should then be doubled, and so on progressively until the expected benefit be obtained, after which the dose should be diminished in the same ratio. No intermission should be permitted whilst the spasms continue. When deglutition is impeded, the opium should be administered per anum, and a solution of it in oil be rubbed upon the spine. Much advantage is derived from rubbing this oily solution on the jaw in trismus — a proof of the direct influence of opium on the nervous system.

In epilepsy, except in cases which are kept up by habit, after the removal of the irritation which first caused the convulsions, opium is not useful. In such cases a large dose is required to break the habit, but a purgative should be given at the same time, as in no disease is costiveness so injurious. The old physicians, even Sydenham, relied much on the influence of opium in chorea; and if the attack be complicated with hysteria, after the bowels have been freely opened, it frequently proves useful. But the plan of treating chorea with powerful purgatives, and afterwards with the carbonate of iron or with the nitrate of silver, is so successful as to leave us little to regret, should opium fail altogether in relieving the disease. In another painful affection also, tic douloureux, opium has so frequently disappointed our hopes, that more reliance is placed on the influence of tonics than on narcotics in this disease.

The watchfulness of maniacal patients early led to the use of opium in cases of insanity: the only objection to its employment is its tendency to cause costiveness; but this is obviated by combining it with aloetics, which operate on the bowels without weakening the soporific power of the opium conjoined with them. By procuring sleep, and thereby severing the catenation of morbid sensations, opium is often highly beneficial in insanity, especially that form of it which is produced by habitual drunkenness. In these cases there is generally a pallid countenance, a cold clamminess of the surface, and other symptoms indicative of great debility, accompanying the want of sleep; under which circumstances the question of life or death is often involved in administering or withholding the use of opium, and in no situation can the judgment and discrimination of the practitioner be more seriously employed.

[The writer's experience has shown, however, that although opiates are trusted to almost solely by some in delirium tremens, they are rarely, or never, indispensable; the disease generally yielding to a proper eclectic and almost expectant treatment. For his experience in the matter, see his *Practice of Medicine*, vol. ii. 277, 2d edit. Philad. 1844.]

In syphilis, opium has been used as the sole means of cure; but although experience has demonstrated that opium cannot be relied upon for this purpose, yet as an adjunct to mercury it is of great value: it enables the system to bear a large quantity of mercury with impunity, and also allays the state of morbid irritability which frequently remains after the cure of syphilis, and, consequently, favours the return of health.

In diabetes mellitus, opium has a powerful influence in restraining the quantity and moderating the saccharine quality of the urine. The dose must be carried to a considerable extent to effect this purpose, to six or eight grains in twenty-four

hours; but too often the evil returns as soon as the dose is diminished. In one case recorded by Dr. Warren, (Transactions of the College of Physicians, vol. iv.,) five grains of solid opium were taken four times a day with evident advantage. Its beneficial influence has been referred to its augmenting the action on the skin, and consequently diminishing that of the kidneys; but as other diaphoretics do not cure diabetes, this theory of its operation is not satisfactory.

Besides the benefit arising from the employment of opium in the diseases already noticed, advantage is also taken of its administration in many morbid states of the system, to lessen irritation, to relieve pain, and to induce sleep; and undoubtedly, whether it be taken into the stomach or applied to the surface of the body, its place for these purposes can be supplied by no other substances. But, like some of the choicest gifts of Providence, it is abused and frequently employed as a poison, and this statement might be closed by tracing the symptoms produced by an over-dose of opium or of its salts, and pointing out the remedy; but for this information we must refer our readers to the article Toxicology.*

Digitalis is generally regarded rather as a diuretic than a narcotic, but under certain states of habit it exerts a decided and important narcotic influence. It operates directly upon the nervous system, producing first stimulant and afterwards sedative effects. This influence of foxglove was first satisfactorily observed by Dr. Hallaran in a case of insanity, in which the tincture of foxglove was given by mistake for the tincture of opium, and from the effects which presented themselves, he was led to conclude that foxglove cannot be advantageously exhibited under "the pressure of high arterial action;" a fact which, indeed, might have been inferred from the repeated observations of its uselessness as a diuretic in dropsy, when an inflammatory state of the habit exists. Dr. Hallaran, taking advantage of his accidental discovery, employed opium as a narcotic in cases of mania, attended with diminished excitement, and the benefit was such as to enable him to remark regarding it, "I am encouraged to proceed with as much confidence in the hope of recovery, as I would in cases of lues, from the mercurial influence." "Insane persons," he adds, "have repeatedly assured me, on approaching to recovery, that they within a very few minutes have had a consciousness of relief, both as to mental and corporeal sensations, from the use of digitalis. One in particular, who for a time had been intent on self-destruction, declared to me that the propensity was never present so long as its efficacy had remained." (Practical Observations on the Causes and Cure of Insanity, by W. S. Hallaran, M.D. p. 107–8.) The mode of administering digitalis in mania is to commence with ten minims of the tincture for a dose, three times a day, in a glass of water, and to add two minims to every dose until sleep be procured, or until nausea or vertigo be experienced, in which case its use should be instantly laid aside, and ammonia and cordials with opium liberally substituted. In this manner Dr. Hallaran has carried the dose "to one hundred drops with safety and advantage;" and the writer of this article has frequently carried it to sixty minims three times a day, with no other result than sleep, quiet, and the restoration of the patient to sound health and intellect. The best form of the medicine for producing these desirable effects is the tincture, made with the recently dried leaves, collected in June, in dry, warm weather, and dried without artificial heat.

In phthisis, digitalis acts also as a narcotic, but it is fitted rather for the advanced than the early stage of the disease. M. Neuman, of Berlin, has extolled its influence as a narcotic in chronic catarrh, when this depends on a state of erethism of the mucous membrane of the bronchi. He gives it in the form of infusion, made with ʒii. of the dried leaves in f.ʒvi. of boiling water, one table-spoonful of which is administered every hour, until nausea, or a sensation of constriction of the throat, or irregular pulse, supervene. The use of the medicine is then suspended for a week, and again renewed if the disease be not removed.

During the use of digitalis its sedative power on the circulation is to be carefully attended to, and its accumulation in the system closely watched, as by carrying it too far and producing extreme debility we may endanger the life of the patient. When the symptoms of poisoning display themselves, (see Toxicology,) in addition to the means already recommended for counteracting them, much benefit will be obtained from the application of a blister to the pit of the stomach. From the difficulty of preserving foxglove leaves so as to retain their active properties, the infusion is a bad form of preparation, and the powder should not be employed unless it retain the beautiful green colour and the peculiar odour of the recently well-dried plant. In prescribing the tincture also, it must be borne in recollection that the bichloride of mercury, corrosive sublimate, and nitrate of silver, are incompatible with it.

Henbane, hyoscyamus *niger*, is very generally employed as a narcotic in all the cases in which opium has been found beneficial. Its active principle is supposed to be an alkaloid, which has been obtained in a separate state, and named *hyoscyamia;* it is taken up both by water and alcohol. The forms in which henbane is administered are tincture and extract. The formula of the London Pharmacopœia for the preparation of the tincture is adequate for every practical purpose; that for the extract might be improved. Mr. Plumbe has procured an extract by macerating one part of the dried plant in four parts of alcohol for four days, filtering the tincture, and evaporating to dryness in a water-bath; it has a beautiful green colour, and retains all the active properties of the plant.

As a narcotic, henbane is analogous to opium in its effects. It operates directly on the nervous system, augmenting the force of the pulse, and increasing the heat of the skin before it produces sleep. It neither confines the bowels nor affects

* The best works on the nature and properties of opium and its salts are those of—Dr. *Christen:* Opium historicè, chemicè, atque pharmacologicè investigatum, 1820.—M. *Charvet:* De l'Action de l'Opium et de ses Principes constituans sur l'économie animale, Paris, 1826.—Dr. *Crump:* On Opium, 8vo. 1788.—Dr. *Leigh:* Experimental Inquiry into the Properties of Opium, 1786.—*Wilson:* Experimental Essays, 1795.—*Degnise, Dupuy,* and *Leuret:* Recherches et Expériences sur les Effets de l'Acetate de Morphine, 8vo. Paris, 1824.

the brain so much as opium. In large doses, however, it operates as a virulent poison, and in some habits excites a pustular eruption.

Although henbane was employed as a narcotic by the ancients, yet Stoerk first investigated its value. He employed it in all painful diseases; and owing to its tendency to relax the bowels, it has been found very serviceable in ileus and colica pictonum, in combination with colocynth and scammony. Mr. Brande recommends it as well adapted for allaying the pain and irritation caused in the kidneys by red gravel. Smoking the leaves in the manner of tobacco, soothes the pain of toothache and relieves the dyspnœa in spasmodic asthma. When applied to the surface, in the form of extract, it dilates the pupil; and much comfort to the feelings of the patient is derived from henbane in the form of a poultice in scrofulous ulcers and open cancer.

The tincture is the best form of administering henbane; but it is most frequently employed in the form of extract. The dose of the tincture is from *m.* xv. to f.ʒiss; that of the extract, from *gr.* ii. to *gr.* xii. Alkalies destroy its narcotic properties; they consequently are incompatible in prescriptions with it, and may be employed as antidotes, when it displays poisonous effects either from an over-dose or from idiosyncrasy.

The results of Stoerk's employment of *conium* in cancer and fistulous sores, recommended it as a narcotic to the attention of modern practitioners. It possesses considerable narcotic powers; but so much depends on the drying and preservation of the leaves, either in their entire state or in that of powder, and on the preparation of the extract, as well as the state of the patient at the time of its administration, that few narcotics have perplexed practitioners so much as conium, and to these causes we must attribute much of the varying opinions respecting its influence as a remedial agent. Keeping these facts in view, conium has been found useful in acute rheumatism, scrofula, syphilis, and especially in cancer, the pain and irritation of which are supposed to be more effectually under the control of conium than of any other narcotic. In these cases the dose should be gradually increased until indications of an overdose begin to display themselves. These are nausea, dimness of sight, headach, drowsiness, vertigo, acceleration of the pulse, sweating, dryness of the mouth, diarrhœa, and, if the system be not relieved, coldness of the extremities, sinking of the strength, and a fatal result. Some, not all, of these symptoms usually present themselves before any perceptible beneficial change in the diseases which have been named is effected by conium. In many of the cases in which conium has proved beneficial, its use has been continued for some time, and the cure has proceeded in the direct ratio of these sensible effects. On this account, the dose of conium requires to be progressively augmented until the symptoms of its influence be sufficiently obvious. The pulse in some instances sinks; in others it is maintained full, and at 100 or more, during the whole time of exhibiting the medicine. Sometimes the function of the kidneys is augmented; sometimes that of the skin; sometimes no effect is produced on the sensibility of the habit; occasionally this is greatly diminished. In that variety of paralysis which is complicated with rheumatism, in which deficiency of motion is attended with acute pain, conium has been found highly beneficial. In six cases of this affection treated with conium in the Edinburgh Infirmary, by Dr. Home, three were relieved and three were cured, although two of them were of long standing, and one in an old person. We have witnessed much benefit derived from it in chronic rheumatism, in keeping down pain; and in chronic sciatica, our experience authorizes us to say that it is more to be depended on than any other narcotic. In intermittent cephalea, conium has been found to be an excellent adjunct to tonics. In scrofula, notwithstanding the testimony of Stoerk in its favour, we have not been able to perceive that it effects more than any other narcotic; and except in soothing the cough, the same character may be bestowed upon it as a remedy in phthisis. In over-doses, besides the symptoms already mentioned, its effects greatly resemble those of opium.

The extract, which is the only preparation of conium in the London Pharmacopœia, is a bad form of the medicine, owing to the difficulty of preserving it; whenever a saline crust appears on the surface, it is no longer of any value. The tincture of the Edinburgh and the Dublin Pharmacopœias is a better form of preparation. We have found it particularly useful, when administered in combination with hydrocyanic acid in a light decoction of cetraria Islandica, in long-protracted hooping-cough, accompanied with much debility, and when the cough is kept up by habit. The dose of the extract is from *gr.* i. to *gr.* vi.; that of the tincture from *m.* x. to *m.* xl., in any bland vehicle.

The atropa *belladonna*, deadly nightshade, possesses considerable influence as a narcotic, and some peculiar properties which require to be noticed. According to the analysis of a distinguished German chemist, M. Brande, its active principle is an alkaline substance, which he has named atropia, and which, in combination with other sulphuric or muriatic acids, is procured in beautiful white prismatic crystals, possessing in a concentrated degree the powers of the plant. The preparation most employed is the extract, which, however, is a very uncertain medicine, unless it be prepared in vacuo, the atropia being volatile and exhaled during the evaporation of the infusion. Belladonna, in whatever form administered, requires to be given in minute doses at first, and then to be gradually augmented until symptoms of its influence on the system become apparent. These are dryness of the throat, vertigo, dilatation of the pupils, slight dimness of sight, extravagant delirium, and an eruption on the skin, closely resembling that of scarlatina.

The efficacy of belladonna has been well ascertained in painful and spasmodic affections: in hooping-cough it has been found useful in doses of an eighth of a grain, gradually increased until the sight is affected, and a scarlet eruption overspreads the skin, accompanied with some degree of headach. Whilst these symptoms continue, the cough ceases, but returns as they disappear; but by renewing this state, and maintaining it for a sufficient length of time, the disease

is always shortened. In neuralgia, both internally administered and externally applied, belladonna has been advantageously employed. The influence of the extract on the radiated fibres of the iris, so as to dilate the pupil, was first proposed as a method of facilitating the extraction of cataract by Professor Reimarus; and for the same reason it is frequently employed for aiding vision during the progress of cataract. A small quantity of the extract, softened with water, is applied upon the eyelid: in a short time the pupil dilates, and the effect continues for many hours. An ointment formed with ʒi of the extract, and ʒvii of lard, affords great relief in the pain of hæmorrhoids; and in chordee when rubbed upon the perineum: the powdered leaves, sprinkled upon cancerous sores, greatly abate the pain of these ulcers. The narcotic influence of belladonna cannot, indeed, be justly depreciated. In prescribing it, alkalies should not be combined with it, as they render the medicine inert; and the same result takes place when the atropia is converted into a tannate, by administering any of the preparations of belladonna with astringent vegetable decoctions or infusions. Dr. Reisinger has proposed to employ atropia, instead of the extract or the infusion of belladonna, on the ground that it exerts a direct sedative influence on the nervous energy, whilst the extract and the infusion exert a primary, stimulant power, like other narcotics.

Belladonna, when given in over-doses, produces such an effect on the stomach that the organ rapidly ceases to be excitable by emetics. Under such circumstances, the advantages of the stomach-pump are great; for it is obvious that, notwithstanding the paralysed state of the organ, we may produce much mischief by inconsiderately augmenting, beyond a certain point, the dose of an emetic.

Like every other narcotic, the activity of belladonna depends greatly on the manner in which it is prepared: in general, so little care is bestowed on the preparation of the extract, that it is difficult to apportion the dose. When the evaporation is conducted in vacuo, as recommended by Mr. Berry, the dose must be considerably less than that usually prescribed.

[*Stramonium, James Town Weed, Thorn Apple*, produces effects like those of belladonna, when taken in large doses. In medicinal doses, it resembles hyoscyamus; but it is not often used internally. In nervous asthma, the smoke is often inhaled with advantage. The leaves are also applied, warm, to painful tumours, irritable ulcers, &c. The extract dilates the pupil, and is employed in the same cases as the extract of belladonna.

Aconite, the leaves of *Aconitum Napellus* and *A. Paniculatum*, Wolf's Bane, or Monkshood, is occasionally used as a narcotic, especially in the form of tincture,—taken internally, and applied externally to the part, in rheumatism and neuralgia. As a sedative, too, it has been prescribed in hypertrophy of the heart. The author has derived great advantage from it, employed in this way, in some obstinate cases of sciatic neuralgia.

The active principle—*Aconitia*—is a most virulent poison, which has been used in similar cases. It is, however, exceedingly expensive, and the drug possesses no virtues over the tincture of aconite. (*New Remedies*, 4th edit. p. 40: Philad., 1843.)

Veratria, the active principle of the seeds of *Veratrum Sabadilla*, *V. officinale*, *Helenias officinalis*, and *Asagræa officinalis*, which are known in commerce under the name *Cebadilla*, *Cevadilla*, or *Sabadilla*, is, like aconitia, a most virulent acro-narcotic. It has been prescribed, internally and externally, in the same cases as aconitia; but its employment demands great caution.]

The genus *lactuca* yields a white proper juice, which has much of the properties, at least of the sensible properties, of opium. When inspissated, this juice, procured from the lactuca *sativa* and lactuca *virosa*, is the lactucarium of the Edinburgh Pharmacopœia. The narcotic properties of lettuce were very early known: Galen, who in the decline of his life suffered from watchfulness, found much comfort in eating lettuce in the evening; and every one who has indulged the same luxury must have experienced the soporific effects of this plant. Dr. Coxe instituted a set of experiments, to ascertain how far lactucarium resembles opium in its medicinal effects; and his results were confirmed by the subsequent experiments of Dr. Duncan. Dr. Coxe's experiments led him to regard lactucarium as precisely the same as opium in its medicinal properties; but although it may be employed as a substitute for opium, in persons who from idiosyncrasy cannot take opium without suffering, yet its properties are not exactly the same. In our opinion, it is one of those substances which may be well spared from the Materia Medica, as the same effects which it produces can be obtained from modified doses of opium. [Its virtues have, in the writer's opinion, been greatly exaggerated.]

Camphor is a narcotic, [?] which, like opium, possesses both stimulant and sedative properties: when it is taken into the stomach in moderate doses, it exhilarates, but in large doses excites nausea, vomiting, and even inflammation of the organ. It is so penetrating, that, independent of absorption, it seems to pervade every part of the frame. It displays its stimulant and sedative powers in nearly the same manner as opium, the stimulant effects always preceding its sedative operation. Its influence is exerted directly on the nervous system, producing sleep and relieving pain; and this is so very powerful that people employed to open packages of camphor have occasionally fallen asleep. As a stimulant, camphor is extremely diffusible, its influence being rapidly extended over the system, and disappearing sooner than that of any other narcotic: it is, therefore, well adapted for procuring a sudden and transitory excitement, in cases in which this is required, and in which its continuance would prove hurtful. When it is intended that it should exert a stimulant influence, like opium, it should be given in small doses, and repeated at short intervals: when its sedative effects are required, it should be administered in large doses, and at considerable intervals.

Camphor may be employed in every kind of fever: in intermittents, during the paroxysm, to allay irritation and procure sleep; in continued fever, to subdue spasmodic twitchings, calm deli-

rium, and remove watchfulness; but in these respects it is inferior to opium. It is, however, an agreeable and useful adjunct to opium in fever. In the phlegmasiæ, camphor is frequently prescribed on mistaken principles, under a conviction that its primary action is sedative. Thus, in ophthalmia, it is sometimes prescribed as an external application in the inflammatory or active stage of the disease; whereas it is only suited for that passive state which is the result of the scrofulous diathesis, and old chronic inflammation of the conjunctiva.

In the exanthematous fevers it is useful for promoting the eruption, and restoring it when it has receded: in confluent small-pox in particular, attended with much of the typhoid character and with petechiæ, it aids in maintaining the powers of the constitution, and the maturation of the pustules; abating the tendency to convulsions which frequently accompanies this form of the disease. One curious result of the external use of camphor is stated by Rosenstein: he says, that if the skin be smeared over with a camphorated ointment, no pustules will appear. In spasmodic affections, camphor may be administered so as to act either as a stimulant or sedative; but in either case it is inferior to opium. In mania, the powers of camphor have been greatly overrated; it lowers the pulse of furious maniacs sometimes to fifty, and an evident sedative effect follows, but without any diminution of their sufferings. "By its duration," says Dr. Hallaran, "the countenance eventually assumes a livid aspect; the extremities also become cold and insensible, and equally livid with the face. The arterial blood seems as if concentrated in the vessels immediately issuing from the heart; the action of the lungs is impeded; and congestion, determining to the head, is often the inevitable consequence. The power of reaction of the heart, under such difficulties, is in fact suspended; and the torpor of the system previously existing is thus greatly aggravated." (Practical Observations on Insanity, &c. p. 130.) Dr. Hallaran thence regards it as a very uncertain medicine in the treatment of mania. In nymphomania, however, camphor has been found highly beneficial; and it is also an admirable adjunct to opium in that variety of insanity which frequently follows a continued course of intoxication.

The opinion that camphor has the power of allaying the strangury which occasionally follows the use of cantharides was first hazarded by Dr. Grainger in the beginning of the last century, and is still credited by many; but it is erroneous: Dr. Heberden, indeed, has demonstrated, that when freely administered camphor causes strangury. The idea that it diminishes salivation is not better founded.

In prescribing camphor, its precipitation from the alcoholic solution, suspended by mucilage in any bland vehicle, is a good form of administering it: or it may be held in solution in water by means of carbonic acid. It has been also successfully used in the form of a vapour bath by some of the continental physicians. The patient is placed on a chair with an open cane bottom, beneath which a chaffer, covered with a plate of iron, is placed; the whole apparatus is surrounded with a blanket, which is pinned round the neck of the patient. A dessert-spoonful of camphor in powder is then thrown upon the iron plate; it is instantly volatilized, and involves the body in an atmosphere of camphor vapour. The patient perspires freely; and in three-quarters of an hour afterwards he may be rolled in a blanket and carried to bed. The sweating must be maintained by tepid fluids. In chronic rheumatism this fumigation should be repeated three or four times a day, and continued for some time after the pains have disappeared. The dose of camphor is generally too small; its narcotic influence being seldom obtained from less than half a drachm: we have given it, with advantage, to the extent of four drachms in the day, in low fever. It operates with more energy when administered per anum than when taken into the stomach: the camphor is quickly felt in the breath; an indescribable uneasiness succeeds, then vertigo, with pallidness of countenance, chilliness, and a low intermitting pulse. Opium, brandy, and ammonia are the means of counteracting these effects of camphor.*

[*Asclepias Syriaca*, Silkweed or Milkweed, and *Lycopus*, Bugleweed, are officinal indigenous Narcotics, but they are not much used.]

We consider it unnecessary to enter more particularly into the consideration of the narcotic agents; the *ethers*, *alcohol*, and some vegetable matters, operate by exerting a direct influence on the nervous energy through the medium of the circulation; but this does not affect their practical utility. It only remains to close our remarks on narcotics with a few statements respecting the influence of what may be termed *mental* narcotics. Mental impressions rouse or depress the nervous energy according to circumstances; we consider those impressions narcotic which at first rouse the system, but by repetition at length exhaust it, in the same manner as stimulant material narcotics exhaust, and induce sleep. *Sound* is one of these mental impressions; but it is necessary to explain that it is not the repetition of sound, but of the same sound, which produces the narcotic effect. When sound is varied, the opposite result occurs, the attention is kept awake; and it is a law of the system that the variation of the stimulus renews the excitement in such a manner, that collapse is prevented for a greater length of time than when there is a repetition of the same sound. It is the monotony of sound, therefore, such as the gurgle of rills, or small water-falls, the voice of a dull preacher, the moaning of the breeze, &c. that is followed by soporific effects; and on the same principle, slow and plaintive music has been found practically useful in the treatment of some peculiar cases of insanity. In this case, the slower, longer-continued, and less varied the impressions are, the more powerful is the sedative influence of the music; and something is also produced by the period of the day and the situation in which the listener is placed. The stillness of evening is highly favourable to the employment of music as a soporific agent;

> "——let the sounds of music
> Creep in our ears; soft stillness, and the night
> Become the touches of sweet harmony."

And when sleep is induced, there is much less

* The best work to be consulted on camphor is the Traité de Camphre, by M. Grauffenaur, Strasbourg, 1822

likelihood of its being disturbed than if it occur during the day. *Gentle friction* and *titillation* produce also soothing effects, on the same principle as the monotony of sound; in cases of pain we have seen them prove useful, by transferring the attention from its seat, to the mild and agreeable impressions of the friction; and this acquires power by joining it with monotony of sound. Thus we know that patting an infant on the back, whilst at the same time the nurse hums a monotonous tune, is almost always sure to produce sleep. Were it requisite, many instances of the beneficial effects of mental narcotics might be brought forward; but enough has been said to show the importance of not disregarding them in cases in which they are likely to prove beneficial.

[The passes and other manipulations of the animal magnetizer induce a like effect, as well as a series of singular and anomalous phenomena, the consideration of which would be inappropriate here.]

A. T. Thomson.

[NAUSEA. See Indigestion.

NAUSEANTS. Although the individual agents in the class of Nauseants belong to Emetics, there is philosophy, as the writer has done elsewhere (See his *General Therapeutics and Materia Medica*, i. 91, Philad. 1843), in separating the consideration of those agents when employed simply with the view of inducing nausea from that of emetics. It has been before said (See Emetics) that the state of nausea is one of reduced action, and hence it can be understood, that if sedation, thus induced, be kept up for a sufficient length of time, it may succeed in subduing inflammation, and the morbid exaltation of organic actions, which constitutes ordinary fever. These effects can be accomplished by nauseating remedies properly administered; and hence but little difficulty is experienced by the practitioner in laying down his indications for the use of nauseants, or in carrying these indications into effect by one or other of the numerous nauseants that are contained in the catalogues of the Materia Medica.

In regard to the condition of the functions under the influence of a nauseant, when carried to the extent of inducing marked nausea, there can be no difference of sentiment; but it has been a question, whether if these same agents be given so as to fall short of inducing nausea, or any sensible evidences of their action—in *alterative* doses, in other words—they may not modify the functions in the same manner as full nauseants, but to a less degree. Much may be said in favour of the affirmative view of this subject, but it is one not easy of demonstration. Were we, indeed, to deny the position altogether, it would be difficult to account for the operation of antimonials, or of many other reputed diaphoretics in small doses, which are emetic in larger. All admit, that when the tartrate of antimony and potassa is given so as to produce nausea, it is a decided sedative and diaphoretic,—diaphoretic because sedative. The state of nausea being, as already remarked, one of diminished action, the exalted vital manifestations constituting fever are reduced by it, and diaphoresis, which had been checked by the febrile irritation, is restored. In such case, the antimonial—like every other diaphoretic, perhaps—is an indirect agent only. But if the tartrate be given in doses somewhat smaller than are requisite to induce nausea, it may still be conceived, that an action of sedation may be exerted, although it must be confessed, that we have no sensible evidence of such an effect except the result; and it must be equally confessed, that in our uncertainty we ought scarcely to place the confidence in those agents which is occasionally done by practitioners. Fortunately, however, this very confidence is, at times, followed by negatively beneficial results. It prevents the partisans of the perturbating treatment of fever, by violent and repeated cathartics, from causing as much irritation as they might otherwise do, and gives the patient a little of that quietude and absence from disturbance, which are so important in the management of all febrile cases, and especially of such as are accompanied by erethism in the mucous membrane of the intestines.

In respect to the therapeutical treatment by nauseants, they are clearly proper in all internal inflammations, as well as in every kind of active hemorrhage; whenever, indeed, it is desirable to diminish the force and velocity of the circulatory movements. In such cases they are amongst our most valuable therapeutical means, and if the system can be kept, for any length of time, sufficiently under their influence, the local hyperæmia will often yield after it has resisted other agencies.

In constipation, a union of nauseants with cathartics becomes occasionally advisable, and, at times, effectual, after cathartics alone have been employed without success. If the constipation be dependent upon any irritated condition of the exhalants of the canal, the use of debilitants, such as these now under consideration, reduces the erethism, and facilitates the operation of the cathartic. Whenever, too, it is desired to break in upon a chain of disordered actions, and especially in the neuroses, nauseants may be beneficially administered; but in these cases the revulsion, induced by a nauseating emetic, is generally preferred, in consequence of the more powerful impression made by it on the nervous system.

The practitioner has to reflect whether the state of the organic actions be such as to require the debilitant agency, which nauseants exert, and it is not generally difficult to arrive at a correct conclusion. Perhaps, in all cases, the tartrate of antimony and potassa is capable of fulfilling the desires of the physician, but occasionally other articles are selected — ipecacuanha, by some; squills, especially when the affection is seated in the air-passages, by others; but there is no sufficient reason for the belief that other nauseants are preferable to the tartrate,—and, moreover, being devoid of any stimulating property, it can be administered in many cases in which the exciting emetics would obviously be improper.

With similar objects nauseants are had recourse to in surgical practice. Whenever it is desirable to depress the energies of the system, and to induce relaxation of constricted parts, they are advantageously employed. In strangulated hernia, tobacco smoke or tobacco infusion is thrown into the rectum; but the use of tobacco, even in these forms, is not devoid of danger, and perhaps there

is no relaxant effect caused by it which might not be equally produced by the nauseants above mentioned.

When a luxated limb has to be reduced, the force of contraction of the muscles is diminished during the existence of nausea; and if the surgeon, at the time, employs his *manœuvres* dexterously, he may succeed in effecting the reduction.

Lastly. — To the obstetric practitioner, nauseants are no less useful. When the tartrate of antimony and potassa is given so as to impress the system, it removes rigidity of the os uteri; and in violent or irritable labour the inordinate activity of the uterus is allayed by it, whilst the dilatation of the mouth of the organ is facilitated. In puerperal convulsions, obstructed and inflamed mammæ, and in puerperal mania, their employment has been found advantageous; but it is needless to point out every affection in which they may be prescribed with benefit. By bearing in mind the sedative influence which they are capable of exerting, the practitioner can meet with little difficulty in deciding upon the cases in which their exhibition may be noxious or salutary.

ROBLEY DUNGLISON.]

NEPHRALGIA AND NEPHRITIS. — In several of the morbid affections incidental to the kidneys the symptoms are, as we have endeavoured to show in a former article, (KIDNEYS, DISEASES OF,) so nearly alike as to render it very difficult, if not impossible, to distinguish between them during the life of the patient. Nor is accuracy of diagnosis of much importance in some of these affections, the treatment of which experience has taught us is to be conducted not only on the same principle, but in the same manner as regards its minutest details. But to distinguish clearly between nephritis—inflammation of the substance of the kidneys, or of their capsules and surrounding cellular membrane—and nephralgia—pain of the kidneys from calculus — is of great moment, since the remedies most proper for the one would be unavailing or injurious in the other. In nephritis, especially in that species where the capsule is the seat of inflammation, bloodletting is absolutely necessary; but in many cases of nephralgia, bleeding would do harm. Again, opiates are not proper in nephritis, at least not till the inflammation has been decidedly arrested; while in nephralgia they are often eminently serviceable from the commencement of the attack.

In order to form this correct diagnosis, let us take the definition of nephritis as we find it laid down by Dr. Cullen in his Nosology, and let us observe wherein it is applicable to both the diseases in question, and wherein it applies to nephritis only. The definition is as follows: "Pyrexia; pain in the region of the kidney, often following the course of the ureter; frequent desire to pass urine, which is either limpid and colourless, or very red; vomiting, numbness of the leg; retraction or pain of the testicle of the same side."

Now, what we are most carefully to attend to in the above definition, is *the pyrexia*—the fever, and the description of fever. All the other symptoms are common to both nephritis and nephralgia; indeed, the *pain* in the latter affection may be much more intense than in inflammation of the substance of the kidney, and quite as severe as when its capsule is inflamed, but the pulse is little, if at all, affected, and the other signs of inflammatory fever are absent. But if, with the symptoms of the local affection, we find a frequent hard pulse, a loaded tongue, great heat, and dryness of skin, we may at once pronounce the disease to be nephritis.

While we are careful not to mistake these two affections of the kidney for each other, we must also be upon our guard lest we confound either of them with certain other diseases which are accompanied with symptoms very similar. They have, for instance, been mistaken for lumbago; but here again the definition will assist us. In lumbago there is seldom much fever; there is no nausea; the urine does not present the appearances which indicate affection of the kidney; in lumbago the pain varies; it is most felt upon resuming the erect posture after the body has been bent, whereas in nephritic affection it remains much the same in every position.

Nephralgia and nephritis may both be mistaken for inflammation of the psoæ muscles; but in inflammation of those muscles there is neither nausea nor retraction of testicle, nor alteration in the flow or quality of the urine; the pain is increased considerably on rotating the thigh, and, if the disease has long subsisted, there is great emaciation.

Nephralgia may be mistaken for enteritis; for, as Dr. Pemberton has remarked, enteritis sometimes commences with such severe pain across the loins as absorbs all other sense of uneasiness; and in nephralgia there is often a sympathetic pain in the abdomen, midway between the os ilium and navel, which is extremely acute, and much increased upon the slightest pressure. We have met with instances where this sympathetic pain has been even greater than that arising from inflammation, and where the lightest possible covering could not be borne without distress to the patient. Now, in a case of nephralgia, should the medical practitioner fall into the error of pronouncing the disease to be enteritis, and proceed to treat it accordingly, that error, though it would prove a sufficiently inconvenient one to the sick person, and would reflect discredit upon himself, might not prove a fatal one; but how lamentable, as well as disgraceful, would be the consequence of his mistaking enteritis for mere nephralgia! The practitioner should, in every case, be cautious; he should put together all the symptoms, and carefully weigh their aggregate force, before he ventures to pronounce a decided opinion upon the disease. In severe nephralgia he will particularly remark, that though the pain and tenderness upon pressure, in the situation above mentioned, are requisite, yet neither the pulse, nor the temperature of the skin, nor the expression of countenance, are those of a person labouring under inflammation of the peritoneal covering of the intestines; neither is there the same obstinate constipation, the bowels being generally acted upon by emollient enemata.

Another disease, with which a nephritic attack is liable to be confounded, is colic. The mistake is not, perhaps, as Galen observes, of much moment, since, at the commencement, the mode of treatment in both is pretty much the same. Still,

however, it is proper to distinguish between them. In colic, the pain is more paroxysmal; there are intervals of absolute ease; there are gripings and distension of the lower bowels; and the pain, instead of being in the loins, and following the course of the ureter, is chiefly about the navel; there is no numbness of the thigh or leg, or retraction or soreness of the testicle.

It is further to be remarked that a pain in the region of the kidney, extending through the ureter, and accompanied by almost all the other symptoms of a nephritic attack, will sometimes take place from hysteria, so that, to adopt the language of Sydenham, it is extremely difficult to distinguish whether these symptoms arise from calculus, or from some hysterical affection, unless perhaps some misfortune having greatly distressed the patient a short time before the disease came on, or the discharge of green matter by vomiting, should show that the symptoms are rather to be ascribed to hysterical than to calculous affection. It is, indeed, very difficult to arrive at any certainty here; we should, however, carefully investigate all the symptoms; we should inquire whether the patient has previously been subject to hysteria; we should endeavour to ascertain whether the uterus and its appendages are in a healthy state, whether menstruation be performed with regularity, and whether the secretion be natural, and we should particularly observe the state of the urine.

Nephritis, as has been already observed, is no otherwise to be distinguished from nephralgia than by the symptoms of inflammatory fever which attend it; and these symptoms will be more or less marked, according as the disease occupies the capsule of the kidney and its surrounding cellular membrane, or its substance. In the former case, there will be pain — burning, pungent, and great — in the region of the kidney; there will be inflammatory fever strongly marked. In the latter case, the pain will be less urgent, — it will be more of a dull, heavy pain, and the accompanying fever will be more moderate; but still the pulse will be more frequent and harder than in a fit of the gravel simply; the tongue will be furred, the skin hotter than natural; the symptoms will be those of subacute inflammation. The former has occasionally been observed as an idiopathic disease; the latter occurs only in consequence of calculi retained in the kidneys, or external injury, or perhaps hydatids. The difference of intensity in the symptoms, depending upon the seat of the inflammation, seems, until of late years, to have been overlooked by authors of the highest reputation.* The late distinguished Professor Gregory, when, in his admirable lectures, he spoke of idiopathic and symptomatic nephritis, appeared to regard both as affecting the substance of the kidneys; he did not, as far as we recollect, throw out any hint of their capsules and surrounding cellular membrane being the chief or the only seat of idiopathic nephritis.

We have thus endeavoured to point out how nephritis and nephralgia may be distinguished with tolerable certainty from each other, as well as from certain affections of the surrounding parts; but no small degree of obscurity yet remains: it is extremely difficult to discriminate between an affection of the kidney itself, and disease of other parts of the urinary system; for one extremity of that system so readily and so rapidly sympathises with the other, that the same set of symptoms will often occur wherever the disease in the urinary organs may be located. Thus, a stone in the bladder may give rise to all the sensations of disease in the kidney, and a calculus in the latter may produce every feeling of disease in the bladder. We would, therefore, impress upon the mind of the young practitioner the importance of extreme caution in pronouncing upon disease of the urinary system.

We now proceed to offer a few observations upon some of the symptoms which belong equally to nephritis and nephralgia; and first, as to the pain generally following the course of the ureter. This pain in the region of the kidney is a very common but not an essential symptom; it sometimes is entirely wanting, and sometimes is so obtuse that it is not noticed, until vomiting comes on and attracts the physician's attention, and induces him to make minute inquiries: in other instances it is extremely severe, yet, upon examination after death, the kidney of the suffering side has been found free from all trace of disease, while the opposite one has been completely disorganized.

Another symptom which is also usually, but not invariably present, is dull pain, or numbness of the thigh and leg. Attention to the distribution of nerves will enable us to comprehend this affection of the lower extremity, as also that of the testicle, which frequently occurs. We have only to bear in mind that the semi-lunar ganglion of either side sends off branches which unite together, and with branches of the par vagum, to form the solar plexus, from which may be traced nerves going to various parts, and among the rest to the kidneys and the testes. The renal and the spermatic plexuses are derived from the same source, i. e., from the great solar plexus formed by the sympathetic and par vagum; and if we trace the sympathetic into the pelvis, we shall find that it is connected with the nerves which pass to the leg. To account for the derangement of stomach, the eructation, nausea, and vomiting which attend nephritic affection, we have also to recollect what nerves concur to form the renal plexus, and what nerve it is that supplies the stomach.

The frequent desire to pass urine may well be explained upon the principle of irritation. The secretion is either scanty, very high-coloured, and mixed with blood, or it is limpid and nearly colourless. The former appearances we may expect to find when calculus is present, or when the affection has been induced by violent horse exercise or by external injury; the latter are more likely to take place in acute idiopathic inflammation. Sometimes there is total suppression, a symptom, as we have shown under URINE, SUPPRESSION OF, to be of very formidable character; it is not, however, necessarily a fatal symptom where the kidneys are primarily affected: we have known it to subsist for above a week in a case of nephritis from calculi, and where the in-

* Boerhaave, for example, says, "*Ipsos renes* verâ inflammatione occupari scimus ex dolore ardente, pungente, magno, inflammatorio, loci ubi renes sunt; ex febre acuta, continua concomitante."

flammation terminated in abscess, as was proved by purulent matter in considerable quantity being passed with the urine. In this case the head was little affected, and though there was great pain, with most distressing nausea and retching, the pulse was hardly more influenced than in an attack of gall-stone.

[A recent pathological writer, M. Rayer, (*Traité des Maladies des Reins*, Paris, 1839,) who considers some form of nephritis an exceedingly common disease, distinguishes four varieties according to the parts of the kidney that are involved; — 1. *nephritis*, where the gland itself is inflamed; 2. *pyelitis*, where the pelvis and calices are the parts inflamed; 3. *perinephritis*, where the inflammation is in the investing membrane; and 4. *pyelonephritis*, when both the pelvis and the granular structure are involved.]

Acute idiopathic inflammation of the kidney may be produced probably by any of the general causes of inflammation, but especially by exposure to cold, or violent exercise on horseback. Cases of this description are, however, of very rare occurrence. It does not appear that Dr. Baillie ever met with an instance of inflammation of the capsule of the kidney; and the late Professor Gregory used to state in his lectures, that he never saw a case of pure idiopathic nephritis. Symptomatic nephritis, i. e. inflammation of the substance of the kidney, or nephralgia with inflammatory symptoms, is, however, far from uncommon. Its most usual exciting cause is calculous matter blocking up the tubuli uriniferi, or calculi formed in the pelvis of the kidney and obstructing that cavity, or the canal of the ureter. But it may also arise from other causes, as from a blow, or a bruise or strain, from severe exercise, long confinement in a recumbent posture, plethora, acrid diuretics, excess in the use of spirituous liquors, poisons.*

There is a great connection between nephritic affection and gout. In some individuals the two diseases make their assault simultaneously; in others they alternate: we find some members of a family affected with gravel, and others with gout; and families have been known where all the men had gout, and all the women gravel. It is to be observed that the former disease is more common in men, owing, probably, to their freer mode of living. The descendants of gouty parents seem to be hereditarily disposed to both diseases. In a family with whose history the writer of the present article is intimately acquainted, the paternal great-grandfather and his wife died martyrs to gout, the one at the age of forty-three, the other at forty-five: their elder son had occasional smart fits of gout till the age of sixty-five, when they left him to return no more till his death, which happened in his eighty-eighth year; his elder son, a man of very temperate habits, never had gout, but died at sixty-six of severe disease of the urinary organs: the two sons of the latter, who have both reached the middle of life, have hitherto been entirely exempt from gout, but both exhibit a disposition to nephritic affection.

Inflammation of the kidney may terminate in any of the ways of other inflammations: it may terminate in resolution; or a profuse sweat, or a copious flow of urine, high-coloured, thick and mixed with mucus, may carry off the disease; or the same may be effected by a considerable discharge of blood from the hemorrhoidal veins. The relief afforded by such a discharge has been noticed by the great father of medicine;† and his commentator Galen observes that the untimely checking of habitual hemorrhoids has given rise to nephritic affection.

To the intimate connection which subsists between nephritic affection and gout, allusion has been already made. That the sudden suppression of the latter may occasion ischuria renalis, or renal inflammation, is well known; and a decided attack of gout supervening upon nephritis may effectually relieve the kidneys. If, however, the symptoms be protracted beyond the seventh day, suppuration will in all probability ensue, and will be declared by its usual symptoms, as frequent irregular rigors, dull, heavy, throbbing pain, &c. The entire kidney may be thus consumed, and in its place may be found a collection of pus: cases of this kind are not uncommon. Again, the inflammation may terminate in an indurated condition of the kidney: its natural structure may be partially or totally lost; it may degenerate into what, by the most skilful morbid anatomists, has been considered a truly scirrhous state, and then permanent lameness may be the consequence. Lastly, nephritis may run into gangrene, as is well attested by Boerhaave and other systematic writers. Such a termination is doubtless extremely rare at the present day; but an example of it has been given by Dr. Turner in the fourth volume of the Transactions of the College of Physicians in London.

We now approach the subject of *treatment;* and, first, of that of pure idiopathic nephritis, which may be disposed of in very few words. The inflammation must of course be met by the same prompt and energetic measures which we are accustomed to employ for the purpose of arresting acute inflammation of other parts. Bloodletting, both general and topical, is a remedy of the first importance, and it should be employed early, and with freedom, lest suppuration or gangrene ensue. The whole of what is understood by the term *antiphlogistic regimen* should be strictly enforced. The warm bath and fomentations should not be neglected. Mild diluents may prove useful; and perhaps some of the class of diuretic medicines, as the infusion of digitalis; but all diuretics which possess a stimulant property should certainly be avoided. It is of importance to unload the bowels, and afterwards to maintain their action; but saline purgatives, being disposed to pass off by the kidneys, are improper in this disease. The mildest laxatives alone should, in the first instance, be tried; such as a draught with one or two drachms of oil of almonds, or castor oil with manna, repeated every third or fourth hour; should this fail, castor oil in a larger dose may be exhibited; or the compound infusion of senna with manna; or, in the event of the bowels continuing obstinately cos-

* A peculiar irritation, it is said, has been produced in the kidneys by arsenic, especially by the fumes of that mineral.

† Τοῖσι νεφριτικοῖσι αἱμόῤῥοΐδες ἐπιγενόμεναι ἀγαθόν. Sect. 6, aph. 11.

tive, recourse may be had to stronger purgatives, as jalap with calomel. It is, however, to be recollected that, owing to the nausea which is so constant an attendant of nephritis, it will frequently be found impossible to administer either oily or other laxatives by the mouth. Emollient glysters, or glysters of warm water only, should then be thrown up, and we should desist from all attempts to administer medicine in another mode until the stomach become more settled. Emollient glysters are useful both as fomentations and evacuants: by this employment we may unload the colon, to unload which is of considerable importance. Blisters have been recommended by some authors of credit, but we should protest against their being resorted to.

If, after the lapse of six or eight hours, the pain and heat in the region of the kidney be not relieved, and the hardness and frequency of the pulse remain, nearly the same quantity of blood should again be drawn from the arm and from the loins by cupping or the application of leeches; and should the inflammatory symptoms still continue, a repetition of the same means may be necessary. We must be guided here, as in acute inflammation of other organs, not by the quantity of blood drawn, but by the impression produced upon the system by its abstraction.

Such is an outline of the plan of treatment to be adopted in pure nephritis. If it terminate in resolution, or by any critical discharge, little will be left for the physician to do afterwards; if, in spite of the most active measures, it run on to suppuration, the treatment must be such as will be hereafter pointed out. If the sudden cessation of pain, hiccup, clammy perspiration, feeble intermitting pulse, great prostration of strength, ischuria, or dark, flaky, offensive urine, indicate that gangrene has taken place, the case is indeed all but desperate; strong cordials and stimulants must then be resorted to: recovery *may* follow, but a fortunate result is a sort of miracle.

In symptomatic nephritis, inflammation of the substance of the gland, from calculi or any other of the causes above enumerated, our treatment must be conducted upon the same principles as in the foregoing species, but, as the inflammatory symptoms are less marked, the same freedom in the use of the lancet will hardly be required at the onset, and seldom will there be need to repeat venesection. Local depletion seems more applicable in this grade of the disease. When, however, the pain has come on very suddenly, and is extremely acute, blood should be taken to the amount of ten or twelve ounces from the arm; recourse should be had to the warm bath or hip-bath; and, if circumstances seem to demand it, local depletion may be subsequently employed. When the disease has been induced by a strain, or blow, or bruise, or by violent exercise, &c., a second bleeding may sometimes be necessary, and a strict adherence to the antiphlogistic regimen will be expedient; but when it appears clearly to arise from calculus, we may generally, after one moderate bleeding, and opening the bowels by mild laxatives, have recourse to opium, in the dose of a grain every second or third hour, according to the urgency of the pain. Opium is in fact the grand remedy in calculous nephritis; it moderates the pain and checks the vomiting, relaxes the spasm, and promotes the descent of the stone into the bladder. If the affection be simply nephralgia, bloodletting will seldom be required; yet if the pain be extremely acute and long-continued, it may be expedient, as a measure of precaution, to take away blood in moderate quantity by cupping from the loins, or even from the arm, since, though none of the essential symptoms of inflammatory action may be actually present, or at least none which we can detect, we can never be sure that inflammation will not supervene, or that it is not already obscurely existing; and we must constantly bear in mind that a degree of renal inflammation, not to be discovered during life, is sufficient to produce abscess of the kidney or a total destruction of the gland.

In nephralgia, having first unloaded the bowels by a brisk cathartic, or, if the stomach be in a very irritable state, by a purgative glyster, opium, in a full dose, and repeated at short intervals, is of great service, and glysters of starch, with laudanum, may also be employed. Every mean should be resorted to to favour the descent of the stone into the bladder, and to afford the patient a chance of its being passed by the urethra. To increase the flow of urine, mild diluent liquids should be freely taken; with the view of relaxing the parts, fomentations should be diligently used; and, as soon as possible, the patient should be placed in a warm bath, and, while in the bath, he should endeavour to pass urine; the attempt will often succeed under these circumstances, though it has failed before. The means to be adopted, by way of obviating a return of nephralgia, are those which have been found most efficacious where the *lithic diathesis* is known to prevail. Alteratives and aperients should be exhibited so as to promote the proper actions of the organs concerned in the digestive process. Five grains of the compound calomel pill may be given every other night, or five or six grains of hydrarg. cum cretâ, with an equal quantity of rhubarb and a grain of ipecacuan. In robust habits we may prescribe from two to three grains of calomel, combined with four grains of James's powder and three grains of compound extract of colocynth and of extract of hyoscyamus, to be taken at bed-time twice a week, and to be followed up the next morning by a Seidlitz powder, or by three drachms of Epsom salts, a scruple of carbonate of magnesia, and six of powdered ginger, in half a pint of tepid water. A tea-spoonful of magnesia in soda-water, or twenty minims of the liquor potassæ in linseed-tea or barley-water may be given twice a day, or more frequently, according to the urgency of the symptoms. But one of the most valuable medicines we possess is the diosma crenata; the infusion of its leaves has often given decided relief to nephritic patients when various other remedies have totally failed.* We have repeatedly wit-

* The diosma crenata has been long known to British botanists as a plant highly esteemed among the Caffres as a remedy in nephritic complaints. It is noticed, upon the authority of Sherard, in Ray's Historia Plantarum, tom. iii. lib. 30, p. 91, under the title of Spiræa Africana, or Buchu of the Hottentots, and is there stated to constitute the principal ingredient of a certain powder in use amongst them—"primarium ingrediens pulveris Cyprii Hottentottorum." It has within the last few years been favourably introduced to the notice of the profession in this country.

nessed its soothing effects, and it appears to possess a tonic property—it seems to give tone to the stomach. It is a valuable addition to the Materia Medica, and merits a more extensive trial and more careful observation as to its effects than it has hitherto received.

[It is recommended by Dr. Joy (Tweedie's *Library of Medicine*, 2d Amer. edit. vol. iii. Philad. 1842) "in chronic diseases of the prostate, bladder and kidneys, gravel, &c.,"—as if the pathological condition to be rectified, were in all these cases identical! *New Remedies*, 4th edit. p. 239, Philad. 1843.]

In cases where there is great weakness of the loins, accompanied perhaps by dull heavy pain, mechanical support will frequently afford great relief. For this purpose a tight bandage may be applied, or a plaster, such as the emplastrum cumini, emplast. ammoniaci, or emplast. oxyd. ferri rubri.*

When an abscess forms in the kidney, it may open in the loins, or it may burst into the pelvis of the organ, and be discharged with the urine. In the former event the aid of the surgeon will be required. If the abscess be of a scrofulous nature, the termination of the case will in all probability be unfortunate. The surgeon will have to deal with sinuses, which will prove very troublesome, yet by means of setons they may sometimes be healed. If the ureters be plugged up with scrofulous matter, there is no chance of a cure, but temporary relief may be afforded; the sinuses opening at an inconvenient part may be healed by seton, and an outlet be made in a more favourable situation. In the latter case, should the abscess be the result of common inflammation, the patient has a good chance of recovery. Balsamics, as the Chian turpentine, may be employed, and the uva ursi may be of service. Should it be, as it commonly is, of a scrofulous character, the prognosis must be unfavourable. In such cases generally the infundibula, pelvis, and ureter partake of the disease; more or less symptomatic fever attends, and the patient is worn out by the irritation and drain. Such, however, is not always the case; patients do occasionally recover against hope, whether by the resources of nature alone, or the aid of medicine, may admit of great doubt; but certainly it is the bounden duty of the medical attendant to bring into the field those remedies which have the reputation of being useful in scrofulous disease — sarsaparilla, cinchona, liquor potassæ, conium, cum multis aliis.

The termination in gangrene is happily of rare occurrence; and when such is the termination, nothing is to be expected from medicine.

We would, in conclusion, impress forcibly upon the minds of persons who have once suffered under an attack of nephritis or nephralgia, the consideration that they are extremely liable to a recurrence of the complaint, and the importance therefore of caution as to diet, exercise, &c. Their diet should be plain and of easy digestion, and repletion should be studiously avoided; they should be sparing in the use of strong liquors, and should especially abstain from acescent wines; they should take regular and moderate exercise; they should not acquire the habit of spending many hours in bed, nor should they make use of a feather-bed; they should avoid exposure to cold and damp, particularly the getting wet in the feet.

H. W. Carter.

* Of these the best perhaps is the emplast. oxydi ferri rubri, on account of its stiffness and adhesive quality, not from any effect which we can suppose the iron to communicate.

NEURALGIA.—The term neuralgia, derived from νεῦρον, a nerve, and ἄλγος, pain, signifies pain in a nerve. The pain is in some cases felt in the cord of a nerve, and follows its track; in other cases the pain is felt in the ultimate twigs into which the nerves split, so that a space, or spot, or organ, and not the track of any particular nerve, aches or is acutely sensible. When it evidently takes the course of a nerve, the case is clear, whatever be the character of the pain; but when it affects an organ, a space, or a spot, we pronounce the disease to be neuralgia from the character of the pain and the absence of such other circumstances as would be sufficient to occasion it.

In the most exquisite cases the pain is excruciating, sharp, sudden, stabbing, or plunging, as patients frequently express themselves; more violent at one moment than another, and sometimes greatly mitigated or absent for a longer or shorter period; induced instantly, like an electric shock, by motion or pressure, even by brushing the point of the finger along the affected part, or it being shaken or blown upon by cold air. Firm pressure is frequently borne, and gives ease. If a secreting organ is in the neighbourhood, it is excited. For example, when some nerves of the face are affected, a paroxysm of pain may be induced by masticating, swallowing, blowing the nose, or even by speaking; and a flow of tears, nasal mucus, or saliva, is frequently observed. If there are small muscles in the neighbourhood, they experience twitchings; and, in the severest cases, large and distant muscles may be convulsed. From these circumstances some have called the disease neuralgia *spasmodica*, but, we think, most improperly, because they are only incidental, and the severest neuralgia may occur without them. The pain may be dreadful and occasion delirium.

Such an affection was formerly called *tic douloureux*, painful tic; the latter word signifying a sudden catching or convulsive motion, such as is noticed in the face or other parts of some persons, and is as it were a local chorea, and such as is noticed in some horses that convulsively bite the manger. Persons with such catchings experience no pain. But when twitchings occur in neuralgia, they are attended by pain, and therefore to their name—tic—in this disease, the epithet douloureux was added. As the disease was first noticed and distinguished in the face, where there is an abundance of small muscles and consequently twitchings usually attend it, the twitchings attracted as much attention as the pain, and the disease obtained its designation from both symptoms. Sometimes, between the shooting pains, there is constant aching; and sometimes the part feels painfully benumbed. We have known the neighbouring parts, which were not in pain, benumbed.

The attacks may last days, weeks, or months; and may recur after intervals of days, weeks, months, or years. They may occur chiefly after

exciting causes, or without any obvious reason. They generally occur without warning, but have been preceded by peculiar sensations and some kind of indisposition. The disease may be suspended or may cease, by nature or through art, or may end in apoplexy, insanity, emaciation, and death.

It most frequently attacks the ramifications of the fifth pair, and the first and second branches of the nerve suffer oftener than the third. We notice it therefore particularly over the orbit, under the orbit, in the cheek where the pes anserinus is spread, in the mouth, and along the lower jaw, and in the lower teeth. Some doubt that it is ever felt in the portio dura; others declare they have known it in that nerve. [It is proper to remark, that after the portio dura has passed through the parotid gland, it is associated with a twig of the fifth pair.] An hospital patient of ours complained of it not only in the cheek, but in the course of the portio dura from the stylo-mastoid foramen. We do not see why the disease should be confined to nerves of sensation. Two, or even all the three, branches, are sometimes affected, and the pain may extend even to the other side of the face. We have known it extend down the neck to the shoulder, and along the inside of the arm to the ends of all the fingers and the thumb. Various nerves of the legs, arms, fingers or toes, are occasionally the seat of the disease; and an intercostal, a lumbar, and even the spermatic nerve, has been attacked. The pain may be confined to one nerve, or to it and its branches, may extend to other nerves in the neighbourhood or at a distance, or it may affect nerves distant from each other, simultaneously or successively, and change its seat backwards and forwards. The pain does not always shoot in the course of the nerve, but frequently in the opposite direction. It may not shoot from a nerve through all the twigs, but only through some.

Neuralgia of this character was perhaps first distinctly described in 1756 by André, the French surgeon of Versailles, in his work upon the diseases of the urethra. Dr. James Fothergill, in the fifth volume of the Medical Observations and Inquiries, published in 1776, described it as occurring in the face, and without being aware that André had anticipated him—and no wonder, when we consider the singular mode in which André promulgated his facts—and he tells us that he never saw more than fourteen instances of it. We have not seen so many. He observed it oftener in women; but this great frequency is not a general fact. He never noticed it in persons much under forty years of age, and this observation, we believe, is confirmed. It is rare in children, yet continental writers record cases of it in subjects but seven and nine years old.

Pain of exactly this character, and not to be accounted for by inflammation or organic disease of the part, now and then attacks organs or spots, and not the track of any nerve. The breast, for example, the heart, the testis, may so suffer; and once we witnessed it apparently in the kidney. The character of the pain, and the absence in the part of the ordinary causes of pain, justify us in regarding it in these cases as neuralgia.

In other cases it is not the character of the pain, but the evident situation of it in one or more nerves, that proves it to be neuralgia. Pain is frequently not stabbing and sudden, not of the description above given, but equally deserving to be called neuralgia, because affecting the course of a nerve. It may be acute, though not electric nor excited by the slightest friction; it may be a constant aching. When a nerve is inflamed, there is great pain. When a portion of a nerve has been seen of an uniform dark red colour after death; when a portion has been found diseased and enveloped in gangrenous cellular tissue; or about double its natural size, of a violet red colour, and strewed with ecchymoses of the size of pin's heads; or a serous, bloody, or purulent effusion has been discovered among its fibres; or nerves have been found hypertrophied and connected with fungous ulcers; when a nerve has been bruised, lacerated, or half divided;—pain of greater or less intensity had been felt in the nerve or the parts upon which it is distributed. (See Abercrombie's Researches on the Diseases of the Brain, &c.) Cotugno, Cirillo, Chaussier, Bichat, &c. have seen similar appearances after neuralgia. In some cases of disease of the brain or spinal marrow, even where paralysis is produced, pain is felt at a distance: the paralysed parts sometimes ache severely in hemiplegia. In epilepsy and hysteria, pain is sometimes felt in the course of nerves. A portion of the pain in structural disease of all organs may occasionally occur in the branches and twigs of the nerves irritated by it. Nerves also frequently suffer pain from rheumatism. There is decidedly a rheumatic neuralgia. The exquisite neuralgia, described as tic douloureux, may arise from those vicissitudes of temperature that occasion rheumatism, and may be rheumatic. But pain, not of that description, though perhaps very acute, perhaps dull and aching as is usual in rheumatism, is every day witnessed in the situation of nerves, in persons who have rheumatism in those situations, and who have been exposed to cold, or perhaps cold and wet; and it yields as readily to the treatment of rheumatism as the ordinary rheumatism of other parts. The neurilema, which is a fibrous membrane, is probably still more affected than the nerve, since rheumatism is chiefly a disease of the fibrous membranes. In rheumatic neuralgia we observe all the varieties of suffering occasioned in other parts by rheumatism: sometimes acute pain, with tenderness, heat, and even throbbing, and aggravation of the pain by heat; sometimes dull aching only; sometimes pain on motion, pressure, or other modes of mechanical irritation; sometimes remittent, intermittent, or even periodical, pain. The pain is sometimes exquisite and sudden, assuming the character of tic douloureux, which, we may remark, not only when rheumatic, but sometimes when not apparently so, may assume a periodical type. It is the clear situation of the pain in a nerve, and not the character of the pain, when it is not like the pain called tic douloureux, that justifies us in rheumatism to pronounce it neuralgic. The nerves chiefly attacked by rheumatism are the sciatic and the branches of the fifth. It is frequently very inflammatory, so that the surface is tender, hot, swollen and even red. Sometimes no marks of inflammation are discoverable, and warmth and

other stimuli relieve. In the case of the face especially, (one side only of which is usually affected, and perhaps not only the nerves, but some of the surrounding parts,) there is a great tendency to periodical intermission, and the paroxysms usually occur in the evening.

In hysterical females, portions of the surface occasionally become exquisitely tender, [*Dermalgia,*] so that the least pressure with the extremity of the finger, such as would not occasion pain were the peritoneum or viscera inflamed,—even the sudden falling of the bed-clothes upon it,—causes anguish. The surface of the front of the body is most frequently affected, sometimes only of the abdomen, sometimes only of the chest; sometimes portions of the back only suffer, particularly at the spine; and sometimes nearly the whole surface of both the trunk and extremities. As no pain is felt while the part is not compressed, perhaps this condition ought not to be called *neuralgia.* But the absence of heat, swelling, redness, and of all signs of internal no less than of external inflammation, and of structural affection and serious disease, the perfect inutility of all the remedies of inflammation, the power of the remedies of pure nervous affection and neuralgia, prove it to be a morbid sensibility of the nerves of touch, and perhaps make it merit the epithet *neuralgic.* Cases of this description are occasionally mistaken for chronic peritonitis and other inflammatory diseases; and, when the tenderness is felt in the course of the spine, it is too often set down as a mark of disease of the spine or its ligaments, or perhaps the whole case is referred to an affection of this portion of the spinal cord, while the morbid sensibility of the spot is merely one of the number of symptoms. We saw this tenderness in an *hysterical* and neuralgic middle-aged *man* who had been exposed to malaria.

The nature of neuralgic affections may be evident during life, and immediately, or not till after a lapse of time; may become evident after death only; or may never be discovered.

Inflammatory conditions of the nerves and structural changes, as well as mechanical causes of irritation, may be detected during life if the seat of these conditions is within the reach of observation: and symptoms may be induced which clearly point out inflammation or structural change, even should these be beyond our observation. Occasionally, however, the seat and cause of the irritation is not only beyond observation during life, though discoverable afterwards, but no symptoms are produced which indicate them. After exquisite neuralgia, or that kind denominated tic douloureux, the cranial bonds have been found of unusual thickness, so that it was fancied that probably they had in some degree compressed the nerves. There is, however, no proof that the neuralgia was the effect of the growth of the bone. The latter might have been only one of several morbid changes going on in the head, and some of which caused neuralgia. The state of all the nerves should have been accurately ascertained. In insanity and idiotism the bones are sometimes of enormous thickness through the general tendency to disease in the head, and the insanity is not ascribable to it, but the whole is the result of the tendency to disease in the head. Here, too, there is generally no neuralgia. To show that in some cases of neuralgia the cause becomes obvious after a time only, we may state that Dr. Abercrombrie quotes one case of exquisite neuralgia of the face that ceased on the removal of a piece of china which had been there fourteen years, and another of ten years' duration that ceased on the extraction of a tooth. [M. Andral (*Cours de Pathologie Interne*) attended a man who suffered agonizingly from neuralgia, which irradiated from the mental foramen. The disease was induced by syphilitic periostosis, and it disappeared as soon as the system was affected by mercury. Such cases M. Andral terms *false neuralgia.*] Sir Henry Halford mentions the case of a lady who laboured under violent tic douloureux till an apparently sound tooth was extracted, on account of the attacks being frequently preceded by uneasiness in it, and that a large exostosis was found at its root. He relates the case of a nobleman who was liberated from the disease by the exfoliation of a portion of bone from the antrum maxillare. To ascribe neuralgia, however, to these causes, in most cases is very unpathological. In ordinary rheumatism, which is not inflammatory, in that form which is unattended by heat, and in which there is mere aching relieved by warmth and all stimulants, and probably greatly influenced by atmospheric changes, the real condition of the part is unknown. The same is true, not only of this rheumatism when affecting nerves, not only of the corresponding form of rheumatic neuralgia, but of that exquisite neuralgia, when not rheumatic, and when no inflammation nor structural change, nor mechanical cause, can be detected before or after death. Good pathological anatomists declare they have frequently been unable to detect any unhealthy appearance, on careful dissection.

[The evidence, afforded by pathological anatomy, is far from being satisfactory. "It is often," to use the language of a modern writer on the subject, Dr. Jolly, "negative, always equivocal, and never decisive." The affection is, doubtless, owing to organic changes in the part affected, as in the case of the various neuroses, but these changes are as yet inappreciable. By many, deductions have been drawn from a few facts, and, therefore, prematurely. Of this character, perhaps, is the view of Mr. Alnatt, (*Tic Douloureux*, &c., London, 1821,) that irritation of the sympathetic nerve is productive of the local mischief, in nine cases out of ten, in the expanded branches of the fifth, or rather the ganglionic nerves, which accompany them.]

Occasionally the pain may be sympathetic, may depend upon no fault of the nerves or even the nervous centres, but upon disorder of the digestive organs. Even such an origin cannot always, in obscure cases, be presumed; and we confess that, allowing some of the blame to be deserved that is laid upon the digestive organs as causing all kinds of diseases of all parts — a vulgar assumption easily made and saving a world of investigation and accurate reasoning,—we have never seen one case of neuralgia referable to such an *origin.*

Since this is true of the nature and causes of neuralgia, we see how various must be its course

and its termination, and how various the prognosis as well as the mode of treatment required in different cases.

[Small tubercles are occasionally developed in the course of nerves, which give occasion to excruciating neuralgic pains. These *subcutaneous tubercles* are distinguished, during life, by an examination of the part affected, when a small body, of the size of about half a pea, is felt under the integuments. A case of the kind occurring in the thumb of a shoemaker, and probably from a puncture of his awl, which was cured at once, after years of suffering, by excision, is related by Dr. Marshall Hall. (*Edinb. Med. and Surg. Journal*, xi. 466; and *Principles of the Theory and Practice of Medicine*, Amer. edit. by Drs. Bigelow and Holmes.)]

[**Treatment.**]—When inflammation is obvious or presumable, whether rheumatic or not, local bleeding, mercury, colchicum, and the whole antiphlogistic plan, general and local, are appropriate. Should these not succeed soon, anodynes may be added; and the pain may, from an inflammatory commencement, degenerate into pain without inflammation, and demand at last solely the treatment of another form of the disease. When rheumatic and yet not inflammatory, the remedies of this form of rheumatism in other parts are required;—stimulants internal and external, tonics, mercury, and all modes of counter-irritation. Coldness indicates stimulants. Among internal stimulants, besides generous diet, the ammoniated tincture of guaiacum is one of the best. It should be exhibited in such quantity and frequency as to keep the patient comfortably warm. A dose of half a drachm may be sufficient, or six drachms may be required; and a frequency of three times in the twenty-four hours may be sufficient, or the dose may require repetition every two hours; and in general both may be diminished after the remedy has been continued for some time, because it stimulates more and more, and its effect lasts longer. When there is debility, and especially paleness, iron in full quantities operates in the most salutary manner, much more so than quinine.

[The oil of turpentine is highly extolled by some. (Copland, art. *Neuralgic Affections*, in *Dict. of Pract. Med.* ix. 891.)]

The hot bath, of water or vapour, the douche, electricity, blisters, moxas, sinapisms, tartarized antimony, croton oil [the ammoniacal preparations of Gondret and Granville; (see art. COUNTER-IRRITATION)], and acupuncture, [electricity, galvanism, and electro-puncture,] frequently cure, if combined with all other appropriate means. Mercury carried to ptyalism frequently cures, provided the strength will bear it, and the rest of the treatment is well conducted. Even the cold shower-bath or cold douche, if followed by good friction, will cure. A warm temperature of the atmosphere around the patient, and warm clothing, may be indispensable. Anodyne narcotics may be absolutely necessary; and the salts of morphia, stramonium, and belladonna [codeia, and cannabis sativa], carried to a due extent, are by far the best, and sometimes alone will cure.

[Aconitia, veratria, and delphinia have been rubbed on the affected parts (see the writer's *Practice of Medicine*, 2d edit. ii. 314, Philad 1844), and occasionally with marked advantage.]

If the disease is seen to depend upon any organic affection, or upon a mechanical cause, the treatment will be evident. Should no structural or mechanical cause, and no inflammation be discoverable, and should the disease be of the exquisite character, then iron is the best remedy. The use of the subcarbonate of iron was discovered by the late Dr. Hutchison of Southwell. The old dose of half a drachm or a drachm will sometimes succeed. But while exhibiting this remedy in various diseases, we soon discovered that it might be given without any inconvenience in far larger quantities than was imagined.* Even children of eight years old will often take half an ounce or six drachms every four hours. If given in twice its weight of treacle, it rarely constipates. But strict attention should be paid to keep the bowels open during its employment, because, being an insoluble substance and bulky, if it is not regularly discharged, its accumulation may be considerable and produce inconvenience. If doses of a drachm every six hours fail, it should not be relinquished till those large quantities also have failed. Although it is the best medicine at present known under these circumstances, it frequently fails altogether, and still more frequently the disease returns, but perhaps yields again and again to it. In all cases of neuralgia, whether exquisite or not, unaccompanied by inflammation or evident existing cause, iron is the best remedy. Probably other forms would answer as well as the subcarbonate. When iron fails, or affords but imperfect relief, it may be serviceable by improving the general health. Less frequently curative as is this medicine than we had hoped from Dr. Hutchison's statements to find it, the power it was proved by this gentleman to possess over the disease induced us to try it in other nervous affections; and in those which are less frequently connected with an inflammatory or structural condition, its power is very great. The first other disease in which we employed it was paralysis agitans, and the first case was cured. In most other cases we have been disappointed, and probably from organic change of the nervous substance frequently existing. The next disease was chorea, and as that is comparatively seldom dependent upon structural change, we have never once failed in curing it with iron, except when it has been partial or of very long standing—circumstances in which structural change is highly probable. Even in two cases of tetanus out of three, we were successful with it; and in the third, which was fatal, there was too little time to exhibit it.

[The cyanuret of iron has likewise been given, as well as the different metallic tonics, the acetate, sulphate and ammoniuret of copper, the oxide and the cyanuret of zinc, &c., but they have not been found equal to the subcarbonate of iron.]

Quinine, arsenic, belladonna, stramonium, colchicum, are said sometimes to cure this exquisite form. The want of attention to the stomach and bowels, and of the observance of good habits, will aggravate it. Relief is said to be obtained occa-

* See a Paper by the author of this article in the 13th Volume of the Med. Chir. Transactions.

sionally by the application of steam to the part, and sometimes by ice. The application of the strongest narcotics, and all irritants and escharotics, as well as the actual cautery, have occasionally done good.

[In neuralgia of the face more especially, the cause of which has been considered by Sir Charles Bell (*Practical Essays*, Edinb. 1841, p. 101,) to be seated primarily in the intestinal canal, and remotely in the fifth pair of nerves, cathartics, especially croton oil, have been recommended; and this, as well as some other forms of neuralgia, would seem to have been removed by it,—doubtless, through the revulsion it excites on the nerves of the intestines; but it need scarcely be said, that it possesses no specific virtue, as has been imagined by some. In the only case of genuine *tic*, in which it was tried by Dr. Christison (*Dispensatory*, p. 382, Edinb. 1842), no benefit whatever was derived from it.

Of late, it has been proposed by M. Allier (*L'Expérience*, No. xvi. Jan. 20, 1838,) to compress the main artery proceeding to the affected part during the paroxysm. (*New Remedies*, p. 182.)]

When all has failed, the division of the nerve, or the removal of the part, if possible, may be proposed, provided no cause in another part is obvious, and provided the pain is invariably limited to one part. Galen was acquainted with the division of the nerve as a remedy in the disease; but a royal French surgeon-maréchal appears to have been the first who performed the operation. Unfortunately it very rarely cures. One portion of the divided nerve suffers again, or the disease reappears in some other part. Too often there has not been even temporary relief. Yet amputation of the finger or thumb, in which the disease was seated, has succeeded, when the cause of the affection was local. (Med. Chir. Trans., vol. iv. and vol. viii.)

When neuralgia arises from malaria, whether ague has also been produced or not, quinine or arsenic, long continued in the largest and most frequent repeated doses that can be borne without the least inconvenience, are the best remedies; and when it is periodical or intermittent, without evident connection with malaria, they are excellent. But sometimes a full dose of extract of stramonium or belladonna, repeated every hour or two from just before the attack is expected to the termination of every paroxysm, succeeds better.

NIGHTMARE. See INCUBUS.

[NIPPLES, SORE. See LACTATION.]

NOLI ME TANGERE, or LUPUS. — The name of *lupus*, which was occasionally used by the older writers on medicine and surgery to signify any ulcer having a destructive tendency, (quasi, voracious as a wolf,) was appropriated to the particular diseases of which we now treat by Sauvages, who considered it a species of cancer, and called it "cancer lupus." The other term by which it is equally well known, is of a still older date; and it is no longer certain in what it originated. Some authors affirm that, the ichorous matter which was formed by the ulcerated parts being supposed to be contagious, this name was given to include an expressive warning to beware the contact of a thing which produced such fearful and unsightly effects. Others state, with greater appearance of probability, that "touch me not" refers to the inutility of using topical remedies in its treatment. However this may be, the terms lupus and noli me tangere are synonymous in British medicine, and have always signified the same thing since they have been used in any definite sense. Biett, indeed, uses the latter term to express malignant ulcers of a cancerous origin; but he will not, we hope, be imitated in this, as this application of it would only serve to add to the confusion which already exists as to the proper comprehension of this disease. We shall revert to this, and to other names which have been used indifferently with it, as we proceed.

There is scarcely any disease of so formidable and obvious a nature about which such uncertain and ill-defined notions prevail. It must have been known to the earliest antiquity. Celsus clearly and forcibly distinguished it from cancer under the name of *cacoethes*; and it is not a little remarkable that the remedies which he recommends are the same which at the present day are most relied on. While other diseases of the integuments have been investigated and described with a minuteness of research which some have considered superfluous, systematic writers have slurred over this with a scanty and superficial notice quite inconsistent with its importance. Some writers pass it over altogether, and others handle it in a manner which gives us as imperfect a notion of the malady almost as if they had left it altogether untouched. This does not surely arise from the rarity of its occurrence, or from the insignificant nature of the affection. A slight acquaintance with the practice of any considerable hospital or dispensary, affords a melancholy proof both of its frequency and its ravages. In Dr. Good's "Study of Medicine" we find the subject despatched in about a page, in which short space he has contrived to insert so much of error, that no person acquainted with the disease could recognise it from his description. Bateman, in his valuable "Synopsis," devotes ten pages to aphthæ; but lupus he is also content to dispose of in one. For the comparative neglect of this subject he excuses himself by stating that he is not aware of any medicine which has been of essential use in its cure. We suspect, however, that one chief reason why the subject has been treated in so insufficient a manner lies in the essential difficulties connected with it. And these are in fact very great. Nature herself does not appear to have assigned in many cases accurate limits to it; at least in the study of these destructive ulcerations, the observers of nature are frequently at a loss to find means for drawing the line of demarcation between true lupus and diseases considered to be of a different pathological nature. In our description of the varieties, or rather species of this malady, we shall observe a somewhat similar plan to that of M. Biett, whose lectures, detailed in the work of MM. Cazenave and Schedel, deliver the best digested history of it to be met with in any language.*

* Abrégé pratique des maladies de la peau, d'après les auteurs les plus estimés, et surtout d'après les documens prises dans la clinique de M. le Docteur Biett, par MM.

Lupus commences by the slow development of a tubercular induration in the tissue of the true skin or mucous membrane; sometimes, perhaps, in the subcutaneous or submucous cellular tissue. According to its situation this tubercle is either single, or else several appear together. While it makes its slow progress towards the surface, the skin takes on a violet colour, which spreads before the advancing tubercle, and seldom yields except to destructive ulceration. After an uncertain time the tubercle makes its appearance on the surface, cracking the cuticle, and forming a coarse laminar scab, from under which exudes a foul ichorous discharge. The crust, which is the surface of the tubercle, is very closely adherent; it spreads and sometimes falls off, exposing an ulceration of a malignant aspect underneath. The latter extends, *pari passu*, with the tubercular crust; but sometimes it spreads beyond the space which this occupies; every time that this falls off, a greater extent of ulceration is visible; and thus it proceeds, unless checked by art, till it commits the most frightful ravages.

This general character of the disease applies to it more particularly when it has its seat on the face, which, in genuine lupus, is the case in nineteen instances out of twenty. But even in this situation it has much variety which a general description cannot include. In describing it more particularly then, we will separately consider it in three forms:—*first*, lupus in which the ulcerative process destroys chiefly in depth; *second*, that in which the destruction and cicatrization do not manifest any open ulceration, and are accompanied by an hypertrophied state of the skin; *third*, lupus which spreads mostly superficially. This division of the subject differs but in the succession from that of M. Biett. It appears the most practical, and therefore the best adapted for closing with the difficulties with which the subject is attended.

1. *Deep or erosive Lupus.*—The first species in our division is that in which the ulcerative process proceeds from the surface towards the centre. We have placed it first because it is the real type of the disease, the undisputed lupus or noli me tangere. The French writers have given to the disease the name of "dartre rougeante" after M. Alibert, who has divided the latter into three species. His *dartre rougeante idiopathique* agrees with this species, which is more especially the lupus of the nose. It very rarely occurs in any other place; but having run its destructive course on that organ, it not unfrequently spreads to the adjacent parts. On the alæ nasi, or at the point, a small tubercle makes its appearance, having its seat more or less deep in the true skin. As it advances, it assumes a livid colour. The skin around it becomes somewhat swollen and painful, and also assumes more or less of a livid or violet hue. After a period, which is various in different cases, a crust forms on the surface of the tubercle, of some thickness, and under this an ulceration extends. The crust falls and is renewed; and at every time that it is detached, it is found that the ulceration has destroyed a deeper layer of the skin. This proceeds very slowly for a long time, the loss of substance taking place nearly insensibly. Although new portions of the incrustation are frequently falling off, and always carry away with them a part of the subjacent tissue, it is not till this process has been going on for a considerable period that the destruction which it has caused is perceived.

In most cases this ulceration is accompanied by a constant discharge, from the nostril of the side affected, of a thin fetid matter. This latter phenomenon may originate in two ways. It may arise from inflammation of the Schneiderian membrane, propagated from the irritation of the tubercle producing the destructive ulceration of the skin. This is a frequent origin of the discharge; and where it is caused in this manner, it is neither so unremitting nor of such a bad quality as in the other case: it partakes here, in fact, more of the character of a common mucous coryza. The other source of the discharge is the actual commencement of the tubercular development in the mucous membrane of the nose itself. It is an indubitable fact that the disease very often commences here. It even sometimes produces much internal destruction without manifesting any morbid alteration in the skin. The history of its progress, when the disease begins in the mucous membrane, is different from that of its cutaneous origin; and we are disposed to think that, not considering this, it has been erroneously stated that it sometimes begins without any tubercular formation. But when we take into account the different structure of the two tissues, the process is quite analogous, whatever apparent difference the first stage of their progress may present. Its beginning in the mucous membrane is after the following manner. After some redness and inflammatory swelling in one of the nostrils, a thin, dark scab forms on the lining membrane, which, if it be torn off, is soon reproduced in the same way as the crust of the external tubercle. The destruction goes on under this thin layer until it corrodes the mucuous membrane and the subjacent tissues just in a way corresponding with that in the tubercles before described. The difference lies not in the character of the disease, but in the nature of the tissues. In the mucous membrane, from its soft, pulpy texture and moist surface,* it is impossible to have the solid induration, denominated a tubercle, which the firm structure of the skin, covered by its dry cuticle, permits, unless by the deposition of a foreign structure, which does not take place in lupus; but there does take place a degree of condensation of its tissue; and in some places where it is most firm in structure, as the hard palate,

A. Cazenave et H. E. Schedel, &c. &c. We wish to acknowledge our obligations to this book. It is written in an unpretending style, but is now justly reckoned, both in this country and Germany, to contain more enlightened information on cutaneous diseases than any other recent work. We cannot but express a wish that Great Britain afforded such an opportunity for the cultivation of this branch of medical study as the Hôpital St Louis at Paris does.

* In other cutaneous diseases a similar relation exists between the mucous membrane and the skin when the former becomes invaded by a disease proper to the latter. Papular eruptions, as lichen, sometimes extend inside the mouth; but here they take on the appearance of aphthous vesicles. In squamous diseases not unfrequently the internal membrane becomes affected; but instead of scales, which, from the nature of the mucous membrane, could not form on it, excoriations take place.

we have known small tubercles to be formed. The crusty exfoliation takes place in both situations; but it is modified as to its density and thickness by the nature of the membrane which secretes it. It is in this form, where the tubercular deposition commences within, that the discharge is sanious and fetid, being in this case the actual secretion from the ulcer; whereas in the former case it is mucus produced, as we have explained, by the irritation propagated to the pituitary membrane.

But whether it be in the cutaneous or mucous tissue that the disease begins, after a short period the progress of it becomes identical. The subjacent cellular tissue and the muscles yield to the ulceration and are destroyed; the cartilages follow in their turn, and very frequently the bones themselves are not protected from its ravages, but partaking in the general destruction, are corroded *pari passu* with the soft parts on the same level. This seems to be the distinguishing property of lupus, and of this particular species more especially. In most other diseases (where there is no actual deposition of morbid structure, as in cancer, &c.) the morbific action affects one tissue in particular, and is more or less confined by its specific irritability to this. But in lupus this does not by any means hold; its ravages have no respect to contrariety of organization: having destroyed the seat of its original development, it continues to eat its way through every tissue which opposes itself in its progress, until its further course is limited either by the destruction of the organ or by artificial means.

To return to the history of its progress. The destruction is generally complete in one of the alæ, or the point of the nose, before it spreads farther on its surface; but sooner or later the disease extends so as to embrace both sides; and wherever it takes up its ground in advancing, it is by the same tubercular deposit with which it began. Sometimes after having destroyed the tip of the nose or one of the alæ, it forms a puckered cicatrix, and seems to be nearly healed up; but it rarely stops in this manner. More generally, after a while, new tubercles become developed in the midst of the cicatrix itself, which ulcerate and destroy with all their original virulence. While the destruction spreads externally in the manner described, in general the internal parts are not exempted from the disease. In the majority of cases some part of the nasal fossa is simultaneously affected with it. The inner surface of the alæ corresponding to the external disease is a common place to find it internally; but the septum narium is the part where its ravages are most generally met with. In such cases the discharge is constant, and becomes an additional subject of disgust to the poor patient. The crusts which collect on the septum and on the turbinated bones nearly block up the passage of the nostrils. Sometimes, indeed, union takes place by adhesive inflammation between the alæ and septum, which has to be divided by the knife and cauterized. Where the disease is not checked by the appliances of art, nature seldom interferes to make its ravages but partial. The soft parts of the nose being destroyed by a gradual external progress, and the internal disease having broken up the septum, the entire organ is thus carried away, and in its stead remains but a square aperture partially divided by a partition, a hideous memorial of its devastating course. The bones sometimes limit its course after it has destroyed all the soft parts; but if it be not arrested before it has gone so far as this, these are also involved. It is at least common for the ossa nasi to be affected; and cases are met with where the destruction invades the superior maxillary bones: usually, however, when the ossa nasi fall, and the septum has been destroyed, it pursues its course no further among the bones.

This is the general account of its ravages, and it seldom stops, unless checked by art, till it fulfils it. Some variety will of course be met with in its course and in its terminations. Instances will be met with where it has disappeared after carrying away one of the alæ nasi; others where it went no further than to carry away the point of the nose. These are singular cases, and will be generally found to have been brought about by art. We have lately seen a case, however, where the ala nasi on one side was taken clean away by the disease, which then stopped spontaneously. In other instances it has run a more superficial course from the beginning, and having eaten through some of the layers of the skin, becomes checked. In such a case it sometimes leaves the nose thinned on the sides, and running into a sharp-pointed tip. It is in these cases that the orifices are liable to be closed by the adhesive inflammation of the internal surfaces.

With respect to the stages of the disease, and the time which they take to run their course, they are by no means definite. The tubercles remain indolent for many months, but when they ulcerate, the disease generally makes quicker progress. No corresponding relation exists between the duration of the malady and the destruction which it produces. While in some it remains without effecting any important loss of substance for several years, in others the whole nose is destroyed in a few weeks.

We must again notice the frequency with which lupus occupies the pituitary membrane. Biett describes with exactness the case where it commences internally, and eats its way from within outwards, its arrival at the skin being preceded by a livid colour. The same author states that it sometimes commences in the skin, and having in its course reached the opening of the nares, it traverses their floor; it then descends along the soft palate, and having destroyed it, returns along the palate bone, eating away the roof of the mouth. But no author has, we think, dwelt sufficiently on the disease as running its course entirely within. It has been long known, indeed, that ulcerations of a bad kind occur at the back of the pharynx, destroying it deeply, and carrying away the uvula and soft palate. These too are often called in surgical works by the improper name of "herpetic ulcers," which infers that they partake of the nature of lupus, as this was and is still too often designated by the term "herpes exedens."* But they often occur in other parts of the nasal

* This name was employed before proper limits were given to cutaneous nosology. To continue to use the term herpes or herpetic in the present day in any other than the vesicular disease so called, only tends to confirm error.

eavity, where they are less obvious; and the insidious lateney with which they commit extensive ravages is sometimes very extraordinary. A great part or the whole of the septum narium may be destroyed without its even being discovered by the patient or by his friends. The chief complaint which is observed is a stuffing in the nose and head, which at length proceeds so far as to alter the voice. This is generally attributed to cold or eatarrh. It is always accompanied by a foulness of breath, which might lead to an investigation of its real source; but this is attributed to worms by the patient's friends; for it is to be observed that this internal lupus occurs almost always in children under twelve years of age.

Its insidious character we have seen strongly illustrated in some cases that occurred in dispensary practice, particularly in two observed by the author's friend, Mr. Smyly. A child, about three years of age, was brought to the dispensary by its mother, who asked for some worm medicine to give it. She said that the child's general health was tolerably good, but that she had a habit of picking her nose, and she was certain that worms was her ailment from her foul breath. Her nostrils were examined, and it was found that the septum was quite perforated by a lupoid ulceration, which reached nearly to its anterior extremity, and extended backwards so far that its termination could not be discerned. Mr. Smyly applied a strong solution of nitrate of silver to the edges of the ulceration, and enjoined that the child should return frequently to have it treated with the necessary vigilanee. She did not return, but was met accidentally, some time afterwards, by Mr. Smyly, who examined the ulceration anew, and found it stationary. She did not go back, she said, because there was nothing the matter with her nose. She had been brought to an apothecary, who gave her medicine for worms, and assured her that this was the whole origin of her complaint. The details of the other case are so remarkably similar, that it would be needless to recount them. Superficial examinations in such cases will often betray the medical practitioner into deep error. We were impressed strongly by the above facts with the necessity for circumspection. In another case of this internal lupus, which occurred to the author last summer, in a girl of fourteen years of age, the voice became completely changed into a nasal tone, and a curious convulsive heaving of the respiratory muscles took place during sleep. A constant coryza, with some fetid discharge, led the author to suspect lupus of some part of the nasal fossa, although nothing could be discerned by inspection. It has lately made its appearance at the root of the nose, near the lacrymal sac, on each side, and confirmed the suspicion entertained of the source of the disease. We notice it for the purpose of calling attention to the effect which the disease appeared to have on the breathing during sleep.*

2. *Lupus with Hypertrophy.* — This form agrees with the first in many points, but its progress and its results are different. Like the former, its seat is frequently the nose, but it does not affect in particular the alæ and tip. It often occurs at its upper part, between the eyes, and on the forehead just above it. The angle of the eye and the cheek beneath it are not unfrequent localities. It may, however, occur on any part of the face, and, according to Biett, even affect the whole face. It begins likewise with tubercles, but they are not like the round hard bodies of the former species. They are rather soft, ill-defined rugosities, having a purplish hue, which spreads from them to the surrounding skin until a circumscribed patch of the latter presents this colour. No open ulceration takes place in the tubercle, but if any single one be watched, it will be found gradually to disappear, leaving a slight furrow behind. This takes place partly by desquamation from the surface, but chiefly by an interstitial absorption going on in the body of the tubercle. Whilst this process is going on in one tubercle, others are growing beside it, and in their turn they undergo the same imperceptible destruction and cicatrization. At the same time the whole unhealthy patch of skin becomes swollen, and presents a peculiar indolent aspect and doughy feel. When this tumid state of the skin goes on to a certain extent, the tubercles are no longer prominent, but the depressions left by the cicatrices are more evident. The base of these often exhibits a white, creamy streak, contrasting with the purple colour of the tubercles, which lie generally on each side of the cicatrices. When the disease, then, is of some standing, it presents the appearance of a swollen, circumscribed patch of the skin, of a violet colour, and in this area there are spots of a deeper hue, denoting the surface of the tubercles, and white marks, the cicatrices of tubercles which have disappeared under the slow process before mentioned.

This form, although also a very chronic malady, spreads more quickly than the first; its manner of extending its limits is the following. On the edges of the morbid surface flat tubercles arise, similar to those by which it at first commenced; their destruction is effected by the desquamation before mentioned, while those inside the area, of an older date, are removed by the interstitial cicatrization. By this double process much destructive change takes place in the tissue of the part

* This singular effect certainly depended on the disease of the nostrils, for the lungs were ascertained to be quite sound by a careful stethoscopic examination. The breathing was performed quite naturally during the day, but the moment sleep came on, the respiratory muscles were thrown into a kind of clonic convulsion, which increased with the intensity of the sleep. The writer was called twice to witness it for the purpose of getting further light as to the nature of the disease. Two things struck us as of peculiar physiological interest in considering this spasmodic action of the muscles of respiration. First, its occurring only during sleep, and secondly, its being confined to one side. The following explanation occurrred to us:—The spasm was remotely caused by the want of free perspiration. The purely voluntary muscles withdrew their assistance during sleep; and the instinctive respiratory muscles having then more to do, they were easily thrown, in a weak, irritable child, into spasmodic action. The spasm having for its end, apparently, the perfect freedom of action of the muscles of one side, and this the opposite side to which the obstruction existed in the nasal fossa, we could not help seeing an analogy between this and the cases where, an obstruction existing in one lung, the patient instinctively lies on the diseased side, to leave the muscles of the sound side perfectly unrestrained in the respiratory motion. If this be a true analogy,—and we were persuaded, whilst considering the case, that it was,—the obstructed state of one of the air-passages of the nose produced a sympathetic effect on the lung and the muscles of respiration of one side,—a striking illustration of the sympathetic consent which subsists between the various parts of the respiratory apparatus.

affected, for although there is no open ulceration, and there seems to be an actual hypertrophy of the skin, the latter has lost all the characters of healthy skin. It is not painful even to slight pressure. It evidently extends to the subcutaneous cellular tissue; indeed it would appear from feeling it, that most of the deposit which constitutes the swelling exists in the latter. This enlargement presents to the touch something of the feeling of elephantiasis; and Biett relates a case where the swelling of the face proceeded to such a degree as to present the appearance of the most frightful form of this disease, with the additional circumstance of the livid hue proper to lupus. Such an excessive tumefaction is, however, a very rare effect of the disease.

It may continue for years without producing any serious consequences of a constitutional or of a local nature, save the existence of the morbid state of the skin just described. Of itself it has not the least tendency to healing. If it does not go on increasing, it remains inert for an indefinite period. It appears to be much more under the control of internal medicine than the former species. When it begins to yield to the action of any remedy, the livid patch of skin, and particularly the tubercles, show signs of an unwonted activity by becoming a little hot and painful, and the colour changing to a deeper red; the hypertrophy then gradually diminishes, and the skin slowly recovers somewhat of its own suppleness and texture, but it never returns entirely to its original state. Its cure has been brought about by the accidental occurrence of an erysipelas, attacking the skin beside the lupoid patch. The encroachment of the inflammation on the morbid structure roused the torpid state of the latter, upon which a new and healthy action followed, which removed the disease.

[M. Andral, (*Cours de Pathologie Interne,*) affirms, that the presence of erysipelas is the most favourable condition for the cure of lupus; and he suggests, that it would be advantageous if we could induce erysipelas artificially in such cases.]

We must here notice a form of the disease in which this second species is complicated with the first. It is as frequently met with in practice as the second form, and is more difficult to deal with, because we have not the same hopes from internal remedies, which are sometimes successfully employed in the latter; nor can we use the local escharotics with the same prospect of advantage as in the first form where the disease is more circumscribed. When the affection is of this compound nature, it begins with a tubercle of the first species, which becomes covered with the crust, as before described. A very ordinary place for its commencement is under the lower eyelid, and here it produces very serious effects by the destruction which sometimes ensues. Tubercles of the character of the second species make their appearance at an indefinite period after those of the first have been going on, and the livid hypertrophy of the skin accompanies it. Here, then, the two kinds of lupus already mentioned simultaneously exist and modify each other. The deep ulceration of the first kind is sometimes cicatrized by the hypertrophic action which accompanies the second species, but still new tubercles from which become encrusted and have the ulcerated character in the adjacent spots. This is the course of a case at present under the author's observation. In a woman aged forty-five, a tubercle of the first species appeared at the angle of the eye; it formed crusts and ulcerated during eight months, when others of a softer nature and more livid colour sprang up beside them; in its progress it reached the edge of the nose, and here took on the character of the hypertrophic lupus; but there always remained one of the tubercles with the crusts and the deep ulceration of the first species;—the disease having spread across the nose, and in one spot sunk so deeply in it that the mucous membrane became affected. About fifteen months after its commencement it developed itself on the hard palate and spread towards the velum. A perforating ulcer, which succeeded to a hard tubercle of the first kind, is now nearly closed by the cicatrization which is going on around it. This case affords a good illustration of the kind of affection which we describe as a combination of the first and second species. The double character of ulceration in depth and hypertrophic cicatrization was evinced both in its first development under the eyelid and on the nose, and in its posterior eruption on the roof of the mouth.

Besides this combined form of the malady, the first and second form may exist separately at the same time. Whilst the hypertrophic lupus is manifested on the forehead or the cheek, the eroding species may be pursuing its course on the alæ or tip of the nose. It is sufficiently common also,—and we should have mentioned this before, as it occurs not infrequently in the first form,—to find pustules of impetigo in the neighbourhood of the lupoid patches. A crop of these impetiginous pustules often form scabs across the nose, while the tip is engaged with the more intractable lupus; but generally there are observed but a few scattered pustules in some locality adjoining the latter, as, for instance, on the nose, lip, or cheek. This complication of lupus has given occasion to some writers to make use of the term impetigo erodens.

3. *Superficial Lupus.*—The third form of lupus is that which ulcerates superficially. Biett describes this species first; and were we to classify the species of this disease according to the comparative frequency with which they occur, we should have followed his example. We have, however, doubts whether this species can in reality be regarded in the light of a variety of the true lupus. It appears to us to differ very widely from the first species, the real *noli me tangere*, which, as we have before stated, is the true type of the disease. It has, indeed, considerable affinity to the second form in external characters, but we think it generalizing too much to consider it as congenerous with the lupus of the nose. As the points of resemblance which it bears to the second form may induce some to regard the latter as a kind of link connecting this superficial ulceration with the first form, we shall give its description here, and superadd some considerations developing our views of its nature.

The history of this third form is not so uniform as that of the last; the superficial destruc

tion which is essentially its character arises variously and proceeds in different ways. The variety which allies it to the second species originates by tubercles, or rather tuberosities, in the skin, large and soft, and differing little from the surrounding parts in colour. These remain for a long period indolent, but as they increase in size, and grow beyond the skin's level, they assume a dusky livid colour, which spreads to the adjacent skin for a considerable space. Ulceration at length commences on the surface of the tuberosities, and as their bases have become by this time nearly joined, as the ulcerative process spreads, it presents often, for a large extent, but one continued surface. A thin ichor is secreted by the surface, which sometimes concretes on the edges into closely adhering scabs; but these are not like the solid crusts which cover the tubercles in the first species. The ulceration has a great tendency to extend its ravages, and in doing so it does not spread by direct absorption of the skin, but by the renewed production of these tubercular indurations which had originated the disease. A circumstance which is remarkable in its history is this—that often, while ulceration breaks out in the new tuberosities, it closes up in the old places, and in this manner it has been known slowly to travel over a great space. The cicatrices which it leaves behind are of the most disfiguring kind, but they are not painful unless pressed upon, or when the patient indulges in spirituous liquors, in improper diet, or excessive exercise. If they be situated where there is a depth of soft parts, they are puckered, and evidently engage the subcutaneous cellular tissue. Even under the best directed medical efforts it is a long time before the ulcerative process entirely leaves these cicatrices. There remains generally at the inferior extremity of the cicatrising surface a spot which refuses to heal, and from this the ulceration is ready to spread again if the medical efforts be relaxed, or from very slight causes. And even when they become perfectly healed, they are often the seat of a new outbreak of the disease. In such instances they become deeper and more extended, and resemble very exactly the scars left by deep and extensive burns. If they occur near any of the natural openings, they may produce much impediment by narrowing these in their puckered growth; and besides this inconvenience, if they occur at the mouth they give rise to a very disfiguring aspect by contracting the commissure of one of the lips, and thus destroying their symmetry. These marks are often observed on the face and neck; and they are not less common on the skin of the thorax and the extremities, where they are often of a very great extent.

Marks of a similar description are often met with which have ensued on a very different process. We find on the face and on the extremities cicatrices which have not been preceded by any tubercle or even by any ulceration. The following is their manner of forming. The skin takes on a reddish hue, and appears a little swollen. After a short time, on this morbid part a slight exfoliation commences, and by this process the skin becomes plainly thinned. When this has continued for a certain period, the skin becomes pale again, and even less coloured than the sound surface adjacent to it. It becomes also smooth and glossy, and this makes a difference between the cicatrices which remain after this affection, and those ensuing upon the tubercles and ulceration, in that the latter are more or less puckered. The cause of this difference is obvious. In the affection we at present describe, the superficial layers of the skin are nearly exclusively engaged in the exfoliation; while, as we have seen, the morbid process is much more deeply seated where the scars ensue upon the tuberosities and ulceration.

There is another affection of the skin, of an analogous character, which deserves to be placed in juxta-position with the last variety. In this the deep layers of the skin and the subjacent cellular tissue are exclusively the seat of the disease. It manifests itself by the skin assuming a livid colour, and becoming hard and stiff. This may remain for many months without showing any actual disorganization. At length, probably by the formation of a small abscess arising from the irritation of the sloughing cellular tissue, the destruction which has been going on in the deep parts of the skin is brought to light. From the opening made by the abscess, which is generally enlarged by the practitioner, if he has not originally made it, a large quantity of sloughing cellular tissue of a yellow colour and firm consistence will be discharged. On the dislodging of these sloughs and the use of appropriate dressings, deep cicatrices slowly form, similar to those above described. The few cases of this affection we have witnessed occurred on the leg. We notice it under the head of the superficial form of lupus, notwithstanding that it affects the deep layers of the skin and the subjacent tissue, because it bears an analogy to it in progressing in a horizontal direction. It appears in fact to differ from the variety last described only in affecting the deep layers instead of the superficial.

These are the varieties of the form of lupus which destroy superficially. Doubtless the chronic nature of its progress, the purple colour which generally more or less attends it, and its frequent origin by what we have denominated tuberosities (to distinguish them from the tubercles of the first form), are circumstances which show a seeming analogy between it and the other species, particularly the second; but notwithstanding these, we imagine that those who have given attention to the subject will think that we are justified in doubting the propriety of making it congenerous with the other forms, at least with the lupus of the nose. It appears to have a different constitutional origin; it is curable by different remedies; and it terminates differently. In several cases of this nature which we have observed, it happened in persons who were at one time the subjects of venereal disease. In some others we think it could be traced to that analogous state of the system produced by courses of mercury. But much more frequently it depends on scrofula. In short it appears to us that it is decidedly a scrofulous disease. This idea is rather strengthened than opposed by what we have just remarked as to its sometimes being found connected with a syphilitic or mercurial taint in the system, as it is known that the sequelæ of mercury or of syphilis are

easily developed in a scrofulous constitution, at the same time that the latter modifies the nature of the resulting affection. The variety of this third form, which spreads by the superficial ulceration of the tuberosities, is evidently the same with the so-called scrofulous ulcer. Biett does not recognise this in terms, but we apprehend that it is easily to be collected from his description of the affection. It is without doubt to this species that Rayer alludes in his list of synonyms, where he enumerates "ulcères scrofuleux, scrophule vulgaire vasculeuse." But it appears of still more importance with respect to the nature of this superficial ulceration to establish its identity with the esthiomenic or corrosive scrofula of M. Lugol, in which the iodine has proved such a powerful agent. And with regard to this we know that some practitioners have been successfully employing this remedy against it without being aware that there existed any doubt as to its scrofulous origin, or that it was included under the name of lupus in the works of writers of authority.* The success of iodine in this superficial ulceration, while it seems an evidence of its scrofulous nature, may be regarded as one criterion of the difference of its nature from the two former species, for against these it is found to possess little or none of the virtues which have given it such a high place in scrofulous affections. Where we state our opinion of the relation which subsists between the two first species and scrofula, it will further appear what connection this third form stands in with the other two.

Having thus described the phenomena and course of the different species of the disease, we have here to mention some particular accidents which its destructive nature sometimes gives rise to from its occurring in certain localities. One of these, which has attracted much notice from its disastrous consequences, is the destruction or eversion of the lower eyelid. This occurs in the first form, or probably still more frequently in that combination of the first and second which we have described. One or two tubercles having formed just under the eyelid, their ulceration perforates the conjunctiva, and goes on to destroy a great part or the whole of the lower lid. Besides the shocking disfiguration which this produces, more serious effects follow. The protection which the palpebræ afford the eyes is by this interrupted; the tears escape through the broken surface instead of by their natural channel; and inflammation of an unmanageable kind ensues, which causes loss of sight on this side by producing opacity of the cornea. The puckered cicatrices sometimes form under the lid, drag it down, and thus produce its eversion. Epiphora and its consequences follow here as inevitably as where the lid is destroyed, if it be not prevented by surgical means, which are more available in this case than the former.

When the nares, the velum, or the palate are the seat of the disease, the voice is always more or less altered. It is only, however, when the destruction is very great that the articulation is entirely lost. Partial deafness is sometimes produced when the disease affects the Eustachian tube, as occurred lately in a case which happened to the author, where the disease spread from the nares and velum. When the disease has its seat in the superior parts of the nasal fossa, it may produce destruction of a fatal nature. Lallemand (Lettres sur l'Encéphale et ses dépendances) is of opinion that in many of the cases recorded by old authors, where abscess of the brain broke and discharged pus by the nostrils, the latter was produced by caries of some of the bones forming the roof of the nares. This is a situation in which lupus occurs more frequently than is at all supposed. The considerations which this writer offers in proof of his positions, are, we think, quite satisfactory, and apply to lupus; for we are persuaded that caries of the bones of the nose is much more frequently the effect of this disease than of all the other causes to which it might be referred. The occlusion of the nares has been already referred to. This event may occur even in the early stages, where the destruction commences by the falling of the crusts from time to time, and all throughout its course there is a tendency in the swollen edges to unite by cicatrization.

Such accidental results of lupus are amongst its most important consequences. Some of them are rare, but it appears highly necessary to know beforehand the tendency to their occurrence, that we may be watchful when the disease exists in any locality exposed to them, if by any means we may be able to devise a treatment calculated to arrest them ere they proceed to such disastrous effects.

There is in lupus little or no sympathetic disorder of the system: it is quite unaccompanied by fever. The gastro-pulmonary mucous membrane, which is so frequently either primarily or secondarily affected in other diseases of the cutaneous tissue, is very rarely affected. The disease may exist for several years, and in this period effect a great destruction, while the general health retains a perfect integrity. Biett mentions that in cases of extreme malignity, where its ravages proceed unchecked by nature or by art, death has been known to happen from the supervention of a chronic gastro-enteritis attended by a slow fever and colliquative diarrhœa. This termination has, however, been so rarely observed that it may be doubted whether the internal affection and fatal result should not be considered as accidentally occurring during the progress of the lupus rather than depending on it. However this may be in certain peculiar instances, it is a well-ascertained character of the disease that its ravages give rise to a remarkably trivial amount of general disorder although it usually happens in individuals of weakly constitutions.

* Confusion must daily occur as to this malady from our inattention to precision in names. Rayer's synonyms are, "Dartre rengeante, herpes esthiomenos (herpes exedens, *Biett*), ignis sacer, formica corrosiva, lupus vorax, noli me tangere. Scrofule vulgaire vasculeuse, ulcères scrofuleux, &c. Every day adds to these, for it would appear that every one relating a case considers that former appellations may be disregarded, and that he may change or add according as some peculiarity of the case or his own ingenuity supplies him with new terms. Thus, in the account of two interesting cases of this superficial ulceration detailed in the Medical Gazette, December 15, p. 367, they are denominated "strumous phagedenic ulcers." A copious supply of names is a proof that the subject has not been reduced to clear limits; but adding to them *ad libitum* only increases the difficulties, and in fact virtually does away with the utility of nosological arrangement altogether.

Causes.—It is very rare to meet any of the varieties beyond the age of forty, so that it is to be considered a disease of youth. Between the ages of six and sixteen it is more common than at earlier or later periods. It appears that the female sex is more subject to it than the male. This has been satisfactorily established to us from the observation of a considerable number of cases. It is also a fact that it is particularly prone to occur in those weakly lymphatic habits in which the period of puberty arrives late, and the menstrual function is feebly performed. Authors assert, and we believe experience proves it to be true, that it is much more common in the country than in town, and in places where vegetables and fruits form the chief food. In the city of Dublin, where the poor are inured to poverty and uncleanliness, it is very commonly met with, although some of the worst cases which are found in the hospitals come from the country parts of Ireland.

Pathology.—The predisposing causes are important elements in considering the pathological nature of lupus; and in treating of the latter we would be understood as particularly referring to our first two species, for we regard the third, as we have before stated, to be a true scrofulous malady. We must consider also that Rayer had in mind this form of the disease exclusively, when he asserted that nearly all the individuals in whom the tubercles of lupus occur have been known to be subject to scrofulous affections in their youth, such as glandular swellings in the neck, groins, or axillæ; for such an incontestable proof of its scrofulous nature can refer only to the superficial ulceration, and can by no means be truly predicted of the first two species. But, although this be the case, we cannot overlook the fact, which is evident from considering the last paragraph, that the state of constitution in which scrofulous diseases manifest themselves, and the circumstances which predispose to their development, are also particularly favourable to the production of lupus. On the other hand, it is also certain that the latter considerations are quite insufficient to establish it as a scrofulous disease, as it is found in persons of quite the opposite diathesis, and more particularly because it resists the remedies which are found so beneficial in scrofula. It was for a long time reckoned to be a cancerous disease; and it would be wrong in a discussion concerning its nature to omit mentioning this opinion. The progress and result of lupus give some colour to the notion of its affinity with cancer. Such loose resemblances, however, have never been sufficient to allow accurate pathologists to recognise their identity. Many of the oldest physicians already marked some of the distinctions between them. Celsus, as we have seen, distinguished them with particular accuracy. Wiseman, and others of our early writers, also laid down excellent rules for making a diagnosis between them. Without entering here particularly into their differences, we content ourselves with remarking that the symptoms, both local and constitutional, are quite different in the two diseases; and that lupus is as decidedly distinct in character from cancer as it is from scrofula.

But notwithstanding that it is impossible to identify it on the one hand with scrofula, as some writers do, or to reckon it as a form of cancer, it seems to us that in searching for its true nature, it may be profitable to recollect the frequency of its occurrence in scrofulous constitutions, and not to lose sight of the circumstances in which it resembles cancer. Now, with regard to the latter, it may be remarked that the hypertrophic state of the skin in our second species is not unlike the deposit of a new tissue, and also that in our first, which we have often laid down as the type of the true lupus, the ulceration is as unsparing in its destructive course as cancer. Besides the true cancer, there are cancerous ulcers which come still nearer the lupus of the nose in character, and cancerous tubercles which differ indeed from the tubercles of lupus in some important particulars, but still they appear to show an approximation in the character of the two maladies. Dr. Jacob has given the history of three cases of an interesting kind in the fourth volume of the Dublin Hospital Reports. Notwithstanding his arguments to prove that they are neither cancer nor lupus, it appears to us that their description answers perfectly to the character of the latter carried to a great extent. At that time the history of lupus was comparatively but little known, and scarcely any good account of it was to be found in books. Ravages to so great an extent are seldom found in this situation resulting from lupus or even from cancer, but the description answers so well to the former disease that no doubt exists in our minds but that it was really lupus.

Were we called on to declare our opinion of the essential character of lupus, we should say that it is an intermediate pathological state between cancer and scrofula, partaking somewhat of the nature of both, but constituting a state in which, by the blending of these two diseases, many of their peculiar characteristics are lost. In the lupus of the nose the double nature appears so proportioned as for each to neutralize the other more perfectly than in any other of the forms; and departing from this on either side, pathological gradations can be traced which degenerate to true cancer on one side, and on the other, passing through the hypertrophic and superficial lupus, lose themselves in scrofula. Besides the considerations offered above in support of this view of its nature, we consider that it is much strengthened by other circumstances, as, for instance, the action of iodine, carbonate of iron, and arsenic on the respective varieties. The first of these is found to possess signal virtues in the third form, which is a scrofulous disease; it is much less useful, if it have any effect, in the second form; and it is quite inert in the first. Whatever powers the arsenic and carbonate of iron possess, are almost exclusively available in the first form; and it may be remarked that, while they have no efficacy in scrofulous diseases, they sometimes are found to palliate affections of a cancerous nature. Although this view of the pathology of lupus has not, as far as we know, been advanced before, we put it forward with some confidence, as we think it accords with the facts which are known on the subject. But the question demands much ulterior discussion, in accordance with that cautious spirit of laudable scepticism which the modern cultivators of medical science have been taught to use in weighing the worth of pathological doctrines.

The influence which a syphilitic taint in the constitution has in the production of lupus acts in two ways. One, the most obvious, is, where it gives rise to a secondary syphilis, assuming the character of lupus, but to be distinguished from it, as we shall immediately point out. Another effect is to predispose to the true lupus. How far these may be really differences only in degree of the syphilitic infection of the constitution, we will not pretend to say, but in practice the two states occur. A striking case, which the author has observed, will illustrate our meaning. A woman, aged forty-seven, came from the country with an extensive lupus of the nose and of the palate; it was that combination of the first and second species which we have described above. She had had primary venereal symptoms seventeen years before, but no secondary disease of the skin, throat, &c. ever followed. She has borne eight children since, of which the first six died either before or immediately after birth. This was the way in which the disease showed itself. She herself attributed the death of her offspring to the contagion of syphilis; and there is no doubt but that she was right, as two of them came away in the putrid state, which is not an uncommon effect of this virus on the fœtus in utero. Her two last children, however, lived and enjoyed good health. The lupus has now existed two years, and has never exhibited any of the external characters of the venereal affection, which it is sufficiently easy to distinguish. This, then, is an instance where the original syphilitic taint predisposed to the formation of lupus, without impressing on it the marks which denote it to be a form of secondary syphilis.

A vague opinion was once entertained that the scanty pus which the ulcerating tubercles supply is contagious, and that it propagates the malady on any part of the body with which it comes accidentally in contact. This notion survived the old error which was so long a time prevalent in the schools, that all pus was corrosive; for even when it became established that purulent matter was a bland instead of an irritating fluid, exception was made in respect of that formed by some kinds of ulceration, and lupus was amongst the number. In fact, it is still imagined by many that the pus which oozes from the ulcerating tubercles is the means by which the slow destruction is effected. That it produces any specific effect as a direct chemical corrosive, is, however, no longer tenable; nor can it even be admitted that any considerable action is to be attributed to whatever irritating properties this discharge possesses. If it drop from the nose upon the hand or arm, it produces no perceptible effect. A patient with lupus of the nasal fossæ, in whom we had an opportunity of confirming this, yet complained of a smarting from it as it trickled through the nose. While, then, it is denied that the pus has any specific agency in the destructive results of this disease, it must be supposed to maintain more or less irritation on the ulcerating surface, as is the case with common ulcers which discharge an ill-conditioned sanies.*

Diagnosis. — It may be easily imagined that the diagnosis of a disease of such obvious characters as lupus will be made with facility. This will be rendered more certain if a clear knowledge of its different species and their stages be kept in mind. But, as it has been often confounded with other diseases, it will give us much confidence in our diagnosis to be forewarned of the affections which might lead us into error. We shall, therefore, point them out briefly with their diagnostic marks.

The pustules which constitute the elementary form in acne are succeeded by round indurations, which have a deeper purple colour than the surrounding skin. When these collect in clusters, as they sometimes do, near the point, or on the alæ of the nose, they have some resemblance to the tubercles of lupus in their first stage, and have been mistaken for them. This error will be avoided by attending to the different nature of the tumours in question. In acne they have been preceded by pustules, some of which are probably still to be met with in parts where the affection is least advanced, and besides this there exists round the base of the tubercle in acne a dull redness from which the lupoid tubercle is quite free, as the latter makes its way slowly over the skin without any marks of inflammation; for the violet discoloration which precedes it does not deserve that name. The hypertrophic lupus, when situated on the nose or forehead, is also not unlike acne, but the history is very different, and even a slight attention will discover the cicatrices which lie between the tuberosities in the former, and thus at once distinguish it.

It might be sufficient to mention the possibility of mistaking the crusts which form in certain kinds of impetigo and porrigo for lupus; but notwithstanding their general dissimilarity, the mistake has been made. The mind is preoccupied with the idea of lupus in every incrusted appearance which is met with in the alæ nasi or its immediate neighbourhood, and these pustular affections sometimes occur here in a very chronic form. In examining the case then, we must search for the primitive form of the eruption which has furnished the crusts. Small pustules will be more or less obscurely detected, with inflammation in the skin diffused between them, if these belong to porrigo or impetigo. Moreover, the crusts which might cause the mistake are quite opposed in their character to those of lupus, being irregular, soft, and easily detached; while in the latter, as we have frequently had occasion to state, they are of a firm consistence, and confined for the most part to the surface of the tubercle which forms them, and to which they generally adhere with great tenacity.

It is stated by authors that the elephantiasis of the Greeks is liable to be confounded with the hypertrophic form of lupus. But the tuberosities which occur in elephantiasis are round, knobby, and of a dusky sallow or fawn colour, which overspreads the whole face. If even they be con-

* See the sixth number of the Edinburgh Medical and Surgical Journal for an account of a curious case related by Dr. Grenville, under the name of "Herpes exedens vermiculatus," in which a very copious discharge which an ulcer furnished was proved by experiment to possess the power of generating the same ulcer in a part inoculated by it. On microscopically examining the pus, it was found to be full of animalculæ of various shapes and sizes.

fined to the face, they spread over it here and there, not affecting (as this form of lupus) the arrangement of a circumscribed patch. In some aggravated forms of this disease the tuberosities ulcerate, and furnish black crusts, which might impose on an unwary observer for lupoid incrustations; but tuberosities will be found, which have not gone on to ulceration, presenting the marks of distinction before laid down. This malady, besides, is rarely confined to the face, and when it has made some progress, it is attended with constitutional symptoms which do not belong to any form of lupus. Finally, its great rarity in this country prevents us from being often put to the necessity of making the comparison, while our knowledge of their points of resemblance will keep us from being off our guard.

Cancer is an affection which must be carefully distinguished. Whether the affinity which we suppose to exist between them be grounded in fact or not, it is of the utmost practical importance to separate the two diseases when we have to consider them with regard to treatment. Some cancerous tubercles commence with a warty tubercle, having a considerable resemblance to incipient lupus. It will, however, be observed that they are for the most part solitary, while the lupoid tubercles are scarcely ever so, at least for any length of time. Their bases too are deep-seated, and attached by a root which ramifies in the surrounding tissue, which is not the case in lupus. The most striking difference is the pain, which, as we have seen, is nearly totally absent in the beginning, and indeed throughout the whole course of lupus. Cancer is the seat of deep lancinating pains almost constantly, which are easily increased by improper applications, and permanently removed by none. Without multiplying points of difference, one more, with those already recited, will be amply sufficient to diagnosticate the two maladies. The circumstance to which we allude is the age of the individual. We have seen, with respect to lupus, that it is a disease of youth; but cancer is seldom or never met with below the age of forty. Biett is desirous of appropriating the name *noli me tangere* to cancerous tubercles, but at the same time insists that it should be carefully distinguished from lupus. We have not adopted his suggestion on this head, because we think it would only serve to confound the affections, which we are desirous with him to keep separate. There has always existed much discrepancy between the French and British ideas of cancer, and it would undoubtedly only serve to increase it were we to assign to this disease a term which has been hitherto uniformly appropriated to lupus.

Syphilis assumes the guise of this malady, as it does that of most other cutaneous diseases. We shall not here discuss the important theoretical question, whether we are to consider diseases of the skin produced by a venereal infection of the constitution the same actual diseases as when they occur unconnected with any constitutional taint, or whether we are to regard them as a class *per se*. For the exposition of this problem we refer to the article Syphilis. It is, however, of undeniable importance to have the means of distinguishing ordinary lupus from that of venereal origin. The crusts which form in the syphilitic affection are much darker coloured than those of the genuine lupus, and the surrounding skin is of a dark copper hue. The tumefaction which more or less attends the real lupus is absent, and the crusts are dry and permanent, and very seldom give place to any open ulceration. If the latter do ensue, it is to be recognised by the well-known characters of the syphilitic ulcer which infallibly attend it, viz.—the deep centre, and the raised, hard, and swollen edges. We have lately seen a case of syphilitic rupia, situated on the point of the nose, which at the first view we mistook for lupus, but on a little closer examination we found that the only point of agreement was the situation of the scabby crust. It was dry, hard, and flat, adhering to the tip of the nose with still greater tenacity than the crust of lupus. There were present also symptoms of venereal affection in the throat, and the patient had had venereal iritis. These were quite decisive of the question in themselves. In investigating doubtful cases, these additional constitutional symptoms should always be sought for, and the history of the disease obtained. But as to the latter, it must be remarked that negative evidence is not to be held decisive, nor is it even of much value if the other marks be present, as it is well known that patients will often refuse to admit the possibility of their having had syphilis, while undeniable proofs of its existence are manifest. There is a syphilitic affection which commences in the cartilages and bones of the nose, and having destroyed them by caries, attacks the soft parts. The bones having yielded, the nose becomes flat, and the alæ expanded. In this state, the affection might be confounded with the hypertrophic lupus, for the root of the nose becomes somewhat swollen and livid; but it will be seen that this description differs from lupus in its progress, its appearance, and its results. It will be unnecessary to compare them more minutely.

Treatment.—The treatment of lupus has, from the earliest periods of medicine, been an object of great importance in practice. It does not put the life of the patient in jeopardy, but the hideous ravages which it effects, and the sure though slow progress with which it marches, render it a formidable disease. Yet, intractable though it be, its sanability by the efforts of medical art is perfectly ascertained. Cases are even to be met with where a spontaneous cure has taken place by the cicatrization of the surface. Where this does occur, it generally belongs to the first form, and the cicatrix is perfect and permanent. There is much less security in the cicatrices of the other species. When the malady is left to itself, such a termination is very rare, and must be regarded as the exception; for the destruction seldom ceases till the nose is nearly level with the face, and then, which is a remarkable circumstance, it sometimes does show a tendency to stay its ravages. In many cases, however, it continues its progress on the cheek to a fearful extent. Experience teaches us, on the whole, to employ the means in our power sedulously and with vigour, and encourages us never to lose hope of arresting its progress; but it also lays before us the difficulties of a most obstinate disease, and cautions us against being too sanguine in our prognosis.

The treatment resolves itself, in this, as in most cutaneous affections, into general and local means. We have seen that the system shows but little sympathetic action in this disease: we should not, therefore, *à priori*, expect that internal remedies would avail much; they form a part, however, of every well-digested plan of treatment. In some cases their efficacy is more considerable, and many cases will occur where they will demand our first and most particular care. On the other hand, the disease will be found in some patients who are in such good general health that it would be inexpedient to lose any time in the exhibition of general remedies. In these the local means will form the main resource, and whatever others may be employed will be directed rather to obviate particular symptoms than to make any impression on the disease through the constitution.

a. Internal Remedies.—When a cachectic state of the system accompanies the malady, if its cause be recognised we must apply all our resources to remove this. If this ever stands to lupus in the relation of cause and effect, it is where it happens in the poor, when indigence exposes them to unwholesome and insufficient diet, with cold and uncleanliness. The low, torpid state of the system which these induce will be evidently best obviated by reversing as much as possible the condition of the patient, substituting a light animal diet, and all the comforts which hospitals and other public or private charities afford. If we can detect any diseased action in the chylopoietic viscera, this will receive a particular attention; for whether this be regarded as a cause or merely as a concomitant effect, no favourable change in the local malady should be anticipated as long as it remains. Gentle aperients and tonics will tend much to the gradual improvement of the system. Occasional doses of the pilula hydrargyri and pilula rhei composita will be a useful remedy when the liver is found to perform its functions torpidly. The old authors, who looked so much to the state of the blood in pathology, attended much to the use of such remedies, and their practice in this disease is not thrown into the shade by any in the present day.

If the individual be obviously of a scrofulous habit of body, he should be kept steadily under the use of appropriate internal remedies for some time. This should be done whatever be the form of the malady with which the patient is affected. But, as we have already stated, the superficial lupus will be the form usually met with in such constitutions, and therefore that for which an antiscrofulous treatment is particularly calculated. For the remedies proper to be used, we refer to the article Scrofula. We may mention here, however, that our experience of iodine has inspired us with great confidence in its efficacy. We have seen striking amelioration produced by the use of the solutions which Lugol recommends. The proto-ioduret of mercury is one of the preparations of iodine which has proved of most utility. The ulceration has been observed to heal under its use with a rapidity which is quite foreign to its indolent character. The fourth part of a grain was given twice a-day to a girl of fifteen years of age, who had a large patch of deep ulceration, with tubercles, on the front of the leg. After ten days of its use, the mouth became affected, contrary to the intentions of the physician, and in three weeks' time an ulceration which had been forming a year and a half was almost cicatrized. We should add that the iodine was used externally, also, as a lotion, and in cataplasms. Its efficacy, however, appears to be confined to the third form, as whatever trials have been made with it in the lupus of the nose, or even in the hypertrophic form, have quite disappointed expectation.

[Iodine, in combination with mercury, has been found especially beneficial. Blasius advises it internally and externally; and it has been recommended highly by Dr. J. W. Schmidt, Jr. of New York. Both the iodide and red iodide were given by him. (*Amer. Journ. of the Med. Sciences*, Feb. 1840, p. 301.) Recently, the iodide of mercury and arsenic has been greatly extolled in the form of the *liquor hydriodatis arsenici et hydrargyri*, or what has been called, from the preparer, "Donovan's solution." (*Dublin Journ. of Med. Science*, Nov. 1839, and Nov. 1842.) It is given internally as well as applied externally, and the writer has found advantage from its use not only in lupus, but in many obstinate cutaneous affections. (*New Remedies*, 4th edit. p. 353: Philad. 1843.)]

The muriate of barytes was commended by Bateman for its efficacy in promoting the resolution of the tubercles. It does not appear to what species the latter belonged in which he employed it, but later authors object to its use, that it is a dangerous remedy from its energetic action on the stomach. The muriate of lime has been proposed as a substitute, having the same properties, and free from these objections. One drachm of the *solutio muriatis calcis* is to be mixed in a pint of water, of which a table-spoonful may be given once or twice a-day at first. This is to be progressively increased after a few days, till ten or twelve spoonsful be taken daily. Preparations of iron have been at various times extolled. The muriated tincture and the carbonate are more relied on than any other. The latter, particularly, has been set forward with a zealous advocacy by writers who confounded the noli me tangere with cancer. It is doubtful whether they are entitled to any confidence in either, but as the cases in which they have been reported to have effected a cure were undeniably lupus, they deserve a trial.

Arsenic is a remedy which has been extensively employed, and the authority of most writers agrees in recommending its internal use. It is found to exert considerable influence in checking the progress of the tubercles, and even in altering the character of the ulcerated surface. It is variously administered. It forms the active ingredient of *the Asiatic pills*, a medicine which enjoys great reputation on the continent.* Fowler's solution is the preparation which is most approved of in these countries. This is to be commenced with the small dose of three drops, to be taken thrice a-day: it may be gradually increased to ten drops, but the greatest vigilance is to be observed during its exhibition. (See Lepra.) Practitioners of merit prefer minute doses of corrosive sublimate,

* They contain about one-thirteenth of a grain of white oxide of arsenic, and somewhat more than half a grain of black pepper in each pill.

carried to the extent of touching the gums, to any other internal means. It would be unprofitable to swell our catalogue by recounting other internal remedies whose effects are more doubtful, and we believe that those above mentioned comprehend all that have gained any merited reputation.

b. External applications.—These form by far the most important part of the treatment, and indeed often constitute the whole of it. It is always in combination with these that the efficacy of internal remedies has been developed, for no one would think of relying on the latter without using some of the local applications which have been at all times the essential therapeutic resource.

The local applications are of two kinds: *first*, those which are intended to exalt the vitality of the part, and thus to promote the resolution of the disease; *secondly*, those which, acting as cauteries, destroy the morbid part, and excite a healthy action in the surface beneath it.

The stimulating applications may be tried where the disease presents itself in the stage of tubercle. The attempt to effect the resolution of the malady will be more feasible in proportion to the earliness with which it is made, and also to the activity which the surrounding skin appears to possess. If the skin show that the circulation is actively carried on, it will be often useful to apply a few leeches to the neighbourhood of the tubercles before commencing the use of the resolvent applications. Dr. Mac Farlane has experienced the good effects of such a plan, and recommends it in these words: "Sometimes the progress of a lupoid tubercle may be arrested and the ulceration prevented by the application of leeches round its base, especially when the tumour is painful and covered by inflamed integuments. This, followed by evaporating lotions and alterative doses of calomel, will not unfrequently subdue the inflammation upon which the progress of the disease depends, and reduce it to that indolent and chronic state in which friction with an ointment, containing the ioduret of zinc or mercury, may be beneficially employed to promote its absorption." These ioduretted ointments are topical applications of decided efficacy; [and the same may be said of creasote ointment, and the tincture of iodine.] Besides these, Biett is in the habit of using the ioduret of sulphur, made, as the metallic iodurets, into an ointment, in the proportion of fifteen grains to an ounce of simple ointment. This is to be applied with gentle friction to the tubercles and the skin surrounding their bases. It stimulates the skin powerfully, and has a greater resolvent effect on the nascent tubercles than any other similar application. Rayer objects to its use in this manner, that it is apt to produce erysipelatous inflammation of the surrounding skin; but this is an infrequent consequence, and when it does occur is not to be deemed an injurious effect; on the contrary, it has been observed to be a means of dissipating the disease by communicating its sthenic action to the torpid tubercles.*

In the hypertrophic lupus the employment of these resolvent ointments is particularly indicated; indeed, in this form our hopes of cure must depend chiefly on such applications, aided by an appropriate internal medication.

[The *oleum jecoris aselli*, codliver oil, may be used in alternation with any of these ointments.]

When the tubercles are once ulcerated, or when they are already far advanced towards this point, those stimulating applications are too feeble to be further of any efficacy. There is one lotion which comes under this head, which some experienced practitioners still confide in; we mean a solution of arsenic of such a strength as to produce only its specific stimulating effects on the sore, in the hope of changing its action. The solution of Fowler contains the arsenic in the best proportion for this application; with this the surface of the tubercles should be sopped twice or thrice a day, when this method is judged expedient. It is generally agreed, however, that it is the wisest practice in such stages to have recourse at once to escharotic applications.

Arsenic is the substance which is almost universally allowed to be the most suitable escharotic which we have the command of in lupus. This has been anciently established, as we find it first on the list of the "*medicamenta adurentia*," which Celsus proposes. Its superiority over the other caustics appears to consist in this, that it produces a slough promptly and certainly, which confines itself to the parts immediately touched by the arsenical preparation. The methods of employing this powerful mineral have been varied by different practitioners. Justamond's application was once a very favourite form. This is made by fusing in a crucible two parts of sulphuret of antimony and one of white oxide of arsenic. The resulting compound, being pulverized, is of a blue colour. Sir A. Cooper is accustomed to use an ointment consisting of white arsenic and sulphur, a drachm of each, mixed with an ounce of spermaceti ointment. He directs some of this to be spread on lint, and to be applied to the ulcer for four-and-twenty hours, at the end of which it is expected that a black slough will be formed, and when this falls, the surface is to be dressed with simple ointment. Other eminent practitioners employ it mixed with simple ointment alone, rejecting the admixture of any other substance to modify its action. When we desire to apply it to indolent tubercles, it is sometimes found that these are covered by a thick cuticle, which impedes its action, for the arsenic has scarcely any effect on the cutaneous surface so long as the cuticle remains entire. Some advise that in such a case a small blister should be raised previous to its application; but this end will be probably better answered by mixing some cantharides with the arsenical ointment. Mr. Adams has successfully employed the following ointment:

℞. Unguenti cetacei, ℥ss.
Oxydi arsenici, ℈i.
Emplastri cantharidis, ℥iii. M. fiat unguentum.

He has also found that the callous edges of an

* See an interesting observation quoted in the Archives Générales de Médecine, t. xxiv. p. 584, where, during the treatment of a lupus of the nose in the state of tubercles, as erysipelas which was epidemic in the ward, attacked the patient's face. It had been very fatal amongst the individuals whom it had seized, but in this patient it proceeded no further than the face, where it ran its course safely, and at its disappearance brought about the complete resolution of the tubercles.

old lupoid ulcer, which had resisted other arsenical applications, yielded a slough freely under the use of this for a few days.

Whichever method may be selected for applying arsenic externally, a certain degree of caution will be requisite. It will be prudent to apply it at one time to no larger a surface than a shilling would cover, and having produced in this space the desired eschar, a new portion may, if necessary, be attacked. This way of proceeding is found to be very effective in establishing a healthy action in the new surfaces, as well as to fulfil the end for which it was adopted, that is, to obviate any unpleasant consequences which might arise from spreading the arsenic over a large surface. While it will be prudent to make use of this remedy with that vigilance which our acquaintance with its powerful action on the animal economy must inspire, it is to be recollected that it is a perfectly safe application. All practitioners who have been accustomed to use it testify that they have never witnessed any of its dangerous effects produced on the constitution by its regulated use. There are indeed two cases mentioned by Dr. Mac Farlane, where, being spread upon extensive ulcerations, it was followed by severe inflammation of the gastro-enteric mucous membrane, apparently in consequence of its absorption into the system. These examples are, however, exceptions, and serve rather to exhibit the rarity of constitutional disorder consequent upon its use; but they also show us the necessity of observing the cautions in applying it which we have suggested.

The arsenical paste is the application which has the most decided caustic powers, and on this account it is by many preferred to the other less energetic escharotics.* In the old cases of extensive destruction the edges acquire a degree of callousness which it requires the most potent remedies to affect; in these it is found advisable to produce a prompt and decided slough with rapidity, as it is found that less energetic means, which act more slowly, only allow of new productions under the imperfect slough, which increase the ravages sometimes to a prodigious extent, of which one of Dr. Jacob's cases is an example. (Dublin Hospital Reports, vol. iv.) In these instances and wherever the strongest cautery is required, the arsenical paste may be used. Its employment demands particular caution not to surpass a limited area in its application, as besides the results alluded to in the last paragraph, it almost invariably causes a severe erysipelatous inflammation of the face. This may in some cases be of little consequence, but it must in all be prevented from running too high by the ordinary means of leeches and proper remedies. Some habits could not safely sustain this. We should, therefore, confine the use of this energetic caustic not only to the kind of ulceration which requires it, but also to individuals whose constitution will enable them to bear the erysipelas which attends its use.

In cases where the effects of the stronger arsenical applications might be injurious, M. Dupuytren recommends a powder, whose action is, he says, specific, not caustic. It is composed of calomel and arsenic in the proportion of one part arsenic to two hundred of calomel. The quantity of arsenic may be doubled if it be required more active. It is sprinkled directly on the ulceration by means of a dossil of lint, or made into a paste with thin mucilage. It is to be left on till it falls away of its own accord, and renewed several times till it produce a new action in the ulcerated surface, and a tendency to cicatrise. This is found to be a very suitable application in children, females, and individuals of a delicate habit and irritable skin. Dupuytren applies it to unhealthy cicatrices, having in the first place produced a new surface by cauterising them, and this appears a very excellent method of employing it. Although this powder is much milder in its action than the other arsenical applications, the same cautions are to be observed in its employment, for whatever is to be apprehended from the absorption of the mineral, may as readily occur from this as from the more concentrated preparations.

The nitrate of silver and the muriate of antimony, which are so commonly used in other ulcerations, seem to be superseded by the arsenical cauterics; but the former does not deserve to be neglected; we can answer for its efficacy in changing the unhealthy surface. The concentrated nitric acid is a favourite escharotic with some experienced men. In that variety of the third form where the deep layers of the skin and the cellular membrane are the seat of the destruction, it is amongst the best applications for causing separation of the sloughs and cicatrisation.

A preparation, called "le nitrate acide de mercure," is in high repute at the Hôpital St. Louis, from the success with which MM. Richerand and Cloquet employ it in producing healthy cicatrices. It is made by dissolving a drachm of the protonitrate of mercury in an ounce of nitric acid. The ulcerated surface is to be touched with it by means of a dossil of lint, and some scrapings of lint moistened with the same solution to be also laid upon the part. Its immediate effect is very painful, but this does not continue. It is also an excellent application for the soft flabby edges of unhealthy, half-formed cicatrices, which, we should remark, are always to be treated with the same energy as the open ulcer; they are certain otherwise to relapse sooner or later into this condition.

[Occasionally, pure creasote has been applied; and Dr. Alexander Ure (*Lond. Med. Gaz.* Dec. 3, 1836; see, also, *Bost. Med. Journ.*, Nov. 4, 1840, p. 215, for a case cited from *Lond. Lancet*) found chloride of zinc speedily check, and permanently cure the disease: he applied it in a paste, made with one part of the chloride and two or three parts of the anhydrous sulphate of lime. One or two applications of the paste were generally sufficient to produce a proper eschar, and when this was detached, the sore was treated with water dressing.]

The actual cautery was formerly much esteemed in this malady, but now is but seldom employed. We believe, nevertheless, that it is sometimes amongst the best methods for obtaining a satisfactory eschar that we possess. It should never be employed, however, in lupus of the nose, for the cartilages become affected by a bad kind

*The arsenical paste is made by mixing the "poudre arsenicale" of Frere Côme with saliva into the consistence of a paste. This powder consists of arsenic, cinnabar, and burnt leather. (See Rayer's Formulaires.")

of inflammation and swelling from its use, which increases the evil. Their defective vitality is not capable of producing a slough. But where the disease occupies a different situation, it is still used with much success.

These methods of destroying the diseased surface are generally preferable to extirpation by the knife, which has, however, been practised with the most favourable result. (Nouveau Bibliothèque Médicale, t. iv.) Cases may happen where it can be had recourse to, in which the mineral escharotics are inapplicable, as, for instance, where a solitary tubercle is situated very near the eye. It is of particular importance to arrest its progress as soon as it can be recognised in this situation; but the cauterising substances would be dangerous applications in the vicinity of the eyeball; so that here, if other things permit it, excision by the scalpel will be the preferable practice.

In employing the escharotic applications, it must be a rule with the practitioner to persevere in their use till the whole of the morbid structure is destroyed. In order to effect this, it will in general be required to repeat them several times, for when the eschar falls, although the new surface present a healthy aspect, the cicatrix may form imperfectly, and afterwards break out again into open ulceration. To diminish the chances of this event, it will be wise not to trust to the destruction of the mere face of the ulcer, but rather to repeat the cautery, to procure a deeper and healthier surface, which will give us better confidence in its cicatrisation. During the progress of the latter, attention must be frequently given to the opening of the nares, as their edges have a great tendency to unite during this process. It is sufficient here to revert to the frequency of this accident, and in individual cases the ingenuity of the practitioner will suggest means to promote or to remedy it.

When the cicatrisation is accomplished, every means should be put in practice to fortify the constitution against the risk of a relapse. To this end it has been proposed to insert an issue or seton in the nape of the neck. This would be, doubtless, particularly in young persons, a wise precautionary measure. It may, however, be stated in general, that if the remedies be steadily persevered with till the malady be quite removed, the cicatrices will stand sound. The Tagliacotian operation has been performed where the nose had been destroyed by lupus. Fears were entertained that the skin taken from the forehead for the new nose would not form a junction with the old cicatrized edges cut to promote union by the first intention, and that the dormant malady might be reproduced by the operation: the union was, however, completely established, and the cicatrix maintained its integrity, because the cure had been complete.

NURSING. See LACTATION.

NYCTALOPIA, Νυκταλοπία, (*th.* νύξ, ὤψ,) *Night-blindness.*—A considerable degree of confusion has prevailed among authors in the use of the term *nyctalopia*. Some have employed it to signify blindness by night, and others blindness by day; while it has also been used indiscriminately to denote either of these conditions. The most approved acceptation, [?] however, among the best and by far the most numerous authorities, would appear to be that of night-blindness, while the opposite condition of blindness by day is properly designated by the word hemeralopia. This is the sense in which the terms are used in the present article.

History and Causes.—Nyctalopia is little known in this country; but in the torrid zone, and in those parts of the globe where the heat and light of the sun are powerful, it is frequently met with. It occurs in Africa, in Asia, and in America, and is said to be more common in China than in Europe. In the East and West Indies, and in the Mediterranean, it is no unusual disease among our soldiers and seamen; and on the eastern shores, and in the islands of the Adriatic, it is at times very prevalent. It has also occasionally assumed an epidemic form in different parts of France, Germany, Poland, and Russia; and in some situations it appears to be endemic.

[The Statistical Report of Surgeon-general Lawson, (Washington, 1840,) shows, that the affection is seen amongst the troops both of the northern and southern posts, but much more frequently in those of the latter. In Florida, it is by no means uncommon.]

Wherever it occurs, it preserves the same characters, varying only, in individual cases, in the severity of its attack, in the length of its duration, or from constitutional peculiarities of the patient.

In persons affected with this disease, when the sun sets, vision begins to be indistinct, and becoming gradually more imperfect as the light diminishes, it is at length entirely suspended. The blindness continues during the darkness of night: in proportion as the day-light returns, sight is restored, and it again becomes perfect when the sun appears above the horizon. Blindness and vision continue, in this way, to correspond with the setting and rising of the sun, and the approach and the remission of the paroxysms are in general gradual; but in some instances the blindness comes on suddenly at sunset, and disappears at sunrise in a similar manner.

The degree of blindness varies. In the early stages of the disease, it is in general partial, and the patient can see objects in a clear light; but as the complaint advances, the powers of vision become more impaired. Some patients are incapable of discerning the moon or the stars, or even the light of a candle, when placed close before their eyes: and some can perceive these bodies, but not the objects which are illuminated by them; while others can barely distinguish light from darkness. After a lapse of time, varying in different cases, the blindness is often complete, and the patient cannot perceive any object after sunset, even in the brightest artificial light.

According to Mr. Bampfield, if the disease is allowed to continue in this degree of severity, the sight will, in the course of time, become weak during day-light, and the eye will not be able to bear the direct or reflected rays of the sun, without pain and temporary blindness being induced. (See Medico-Chirurg. Transactions, vol. v. p. 39; also Manardi Epist. lib. xv. Epist. ii. p. 431.)

Such cases, however, are not of common occurrence.

But even when this irritable state of the eye has not been induced, it would appear that, on some occasions, the patient, when placed in an obscure situation, (Radii Scriptor. Ophthalm. Minor. vol. iii. p. 176, 177, 179, 192. Lipsiæ, 1830,) is incapable of distinguishing objects by day as well as by night; but this state does not seem to have been often remarked, and it would appear that a condition exactly the reverse of this has also been sometimes observed. (See Lettres Edifiantes, tom. xxiv. p. 434.)

In general, there is no uneasy sensation or visible alteration in the eye, to indicate the presence of any morbid affection. Some authors, however, describe the pupil as being immovable and contracted; whilst others say that it becomes immovable and dilated, particularly during the night. These discordant accounts may, perhaps, have arisen from examinations of different states or stages of the disease; for Mr. Bampfield, whose opportunities of observation were extensive, says, that after it has continued long, and in the worst stages, the pupil is often contracted, and the eyes and actions of the patient evince marks of painful irritation, if the eyes are exposed to a vivid light, or if he look upwards." In another place he observes, "the pupil of the eye is considerably dilated both by day and night, in the proportion of about one case in twelve, and at night the pupil is often dilated, and does not perform its expansions and contractions when exposed to the moon or artificial light." (Medico-Chirurg. Trans. loc. cit. p. 42.) These were also generally cases which had been long protracted.

Although no medical treatment has been employed, the disease, after continuing for a longer or shorter period, frequently undergoes a spontaneous cure. In temperate climates, its usual duration is from one month to six weeks; but within the tropics its continuance is generally much longer, extending from a few weeks to three, six, or nine months, and even occasionally to a still longer period. On some occasions it would appear to be congenital;* and it is also alleged to be at times hereditary. (Rees's Cyclopædia, art. Nyctalopia.)

The natives of cold countries who reside within the tropics are said to be more subject to this complaint than the indigenous inhabitants; and those Europeans who have once had an attack are very liable to a recurrence of it while they remain in a warm climate.

Within the tropics, the disease may be almost considered as endemic, and does not appear to be more prevalent at one season than another. But in temperate climates it most generally occurs during or after the protracted heat and dazzling light of summer and autumn. In Germany it prevailed as an epidemic in the months of July and August; ("Calore solis existente maximo— remittente solis æstu desiit hæc nyctalopia." Halleri Disput. loc. cit. sect. 8.) and in Russia Dr. Guthrie says it is most frequent in June and July during the hay-harvest. (Edin. Med. Comment. decad. ii. vol. ix. p. 288.) All the cases which the writer of this article met with in the Mediterranean took place in the end of summer and in autumn. It is, however, by no means confined to those seasons. Hippocrates names it among the diseases that occur "circa brumam," and adds that the greater number had relapses "ante æquinoctiam." (De Morb. Vulgar. lib. vi. sect. vii.)

Even at the season of the year when the heat has not arrived at its greatest height, but when the sun is long above the horizon, the disease has appeared as an epidemic among troops exposed to much watching and fatigue. The most remarkable instance, perhaps, is that recorded by Dr. Guthrie in the Edinburgh Medical Commentaries. "I was lately desired," he says, "to give an opinion on a curious phenomenon that happened last war in Finland, where a Russian detachment, ordered to attack a Swedish post during a light night in spring, had like to have mistaken one another for enemies, and occasioned bloodshed, owing to some hundreds in the column being *blind after sunset*. The complaint seized the soldiers in spring, when the nights, from the short absence of the sun, and the strong reflection from the snow, must have been very fatiguing to the eyes, at a period of much martial vigil and alarm; surprises on both sides being then very frequent, more especially nocturnal." (Edin. Med. Comm. loc. cit. p. 285 et seq. See also Ephem. Natur. Curios. dec. iii. Ann. vii. and viii. append. p. 131.)

Night blindness has been described as endemic in different countries. We have an interesting account by Chamsem, (Hist. et Mém. de la Société Royale de Médecine, ann. 1786, Paris, 1790) of its annual occurrence in this form in France, at Roche Guyon and the neighbouring villages, in some of which it occasionally affects as many as one in nine or ten of the inhabitants. It appears every year in spring, about the middle of March, and continues for three months; sometimes also returning in the autumn. The soil is here composed of chalk and marl, upon beds of burrstone (meulière) and flint (caillou), and the disease principally attacks those who are much exposed by their labours in the fields to the reflected heat and light from this dazzling surface. As the summer advances the ground becomes covered with verdure, and being no longer capable of reflecting the brilliant light of the sun, the disease disappears for the season.

According to Richerand, the inhabitants of the northern regions, where the ground is covered with snow during the greater part of the year, become, at an early age, the victims of this disease. He also says that among artisans the same morbid state of the vision is sometimes produced from long exposure to a great intensity of artificial light. (Elements of Physiology, p. 284, edit. 1812.)

Nyctalopia is a disease more common to the labouring classes of people, and those who are exposed to much fatigue, watching, and other debilitating influences—whose diet is often scanty

* See a case where the patient, 20 years of age, had had the disease "from the first time he was able to take notice of things." Philosoph. Transact. vol. iii. p. 38. Also the case of a patient, 23 years old, who states, "se a quatuor jam annis laborare cæcitate nocturna." Halleri Disputat. tom. i. disp. xxii. sect. 2. Lausannæ, 1757. Also an account of its occurring in three individuals of the same family, in Radii Scriptor. Ophthal. Minor. loc. citat.

or even unwholesome. (*Haller.* Disput. loc. cit. sec. xx; Gregor. Horstii Oper. Med. tom. ii. lib. ii. obs. 34. p. 106; also *Chamsem*, op. cit. p. 139.) The epidemics which are referred to above were confined to persons of this description; and its frequent occurrence among our seamen leads us to the same conclusion. A few instances are recorded of its affecting individuals among the better ranks, but in such cases the habits and mode of life of the patients have not been described with precision, so as to justify us in forming a different opinion.

In many cases nyctalopia appears to be a purely local or idiopathic disease; but still more frequently it is the consequence, or at least the concomitant, of some other affection. All the instances of it which came under the observation of the writer, happened to individuals more or less affected with sea scurvy; and several medical authors and surgeons of the navy have remarked the frequent co-existence of the two diseases.*

It is very often symptomatic of derangement of the digestive organs, so much so that Scarpa, (*Scarpa*, Mallatie degli Occhi, p. 252. Pavia, 1801.) Schmucker, Richter, and several other authors, seem to consider the disease as almost entirely originating in this cause.

Some morbid condition of the brain would likewise appear to be occasionally present; for headach and vertigo, pain and watering of the eyes, &c., have been enumerated as precursory or concomitant symptoms.†

Hippocrates (Op. cit. Prædict. lib. ii. sect. ii. p. 110) and Celsus (De Medic. lib. vi. cap. vi. p. 369. Lugd. Bat. 1730) state that females, whose catamenia are regular, are not subject to attacks of this disease; but later observations sufficiently prove the general inaccuracy of this opinion. It is indeed true that the proportion of males affected is in general greater than that of females; but this arises from the circumstance that the latter are usually exempt from the same degree of hard labour in the fields, and other debilitating causes. For similar reasons young children are seldom affected by it.

Persons of different temperaments are equally liable to nyctalopia; and it is not peculiar to those who have eyes of any particular size or colour.

Nyctalopia has been attributed to various other causes, such as eating rice, sleeping in the sun, the use of poisonous vegetables, a fit of anger, (Lettres Edifiantes, loc. cit. p. 434,) &c. It appears from Haller (Disput. loc. cit. sect. xxi.) that the inhabitants of Bavaria ascribe the disease to the use of bread in which darnel is present; and this opinion is one of great antiquity; for both Virgil‡ and Ovid§ mention that "lolium" was believed to be hurtful to the sight; and Plautus‖ expressly says that it produces nyctalopia.

[In very rare cases it would seem to be a congenital affection, and capable of being transmitted from father to child. In such cases there must, of necessity, be a peculiarity of organization. M. Cunier (*Annales de la Société de Médecine de Gand*, 1840, and *Lawrence on Diseases of the Eye*, Amer. edit. p. 541, Philad. 1843,) has published the history of a family in which it appears to have been transmitted, by hereditary descent, through six generations.]

Pathology. — In order to produce distinct vision, a due proportion of light is necessary to excite the retina. The quantity required for this purpose depends much on the impressions which have been previously made on the organ. When the eye has been exposed to a strong light, a fainter illumination will not suffice to enable it to discriminate objects; while, on the other hand, vision will be painfully acute, even in a comparatively obscure light, to those who have previously been in a state approaching to entire darkness. Thus the prisoner becomes gradually enabled to perceive the objects in his cell; while the man who has been exposed to the reflection of the sun's rays from the snow is rendered for some time incapable of seeing in the less dazzling though clear light of day. From the operation of the same law, the eye, in nyctalopia, after being exposed to a long and brilliant sunshine, is not excited by the feeble light which continues after sunset, and vision entirely ceases.

When an organ is often and highly stimulated, its sensibility, it is well known, becomes impaired. The long-continued action of light accordingly produces a state of torpor or insensibility of the retina, which becomes greater in proportion to the degree of predisposition and length of time during which the exciting causes continue to operate. In the early stages of the disease, before any considerable insensibility of the retina has been induced, vision is observed to be more or less perfect in a clear light, and according to the degree of illumination. But after a lengthened attack, the increasing torpor of the retina renders it insensible to the stimulus of even a bright artificial light. While this torpid state of the organ remains, the pupil continues dilated and immovable on the approach of a light which is not of sufficient intensity to excite the retina in the degree requisite to produce vision.

Nearly the same explanation applies to that state of protracted disease in which the eye has become unable to bear the direct or reflected rays of the sun. The heat and light which occasion the insensibility of the retina, at the same time stimulate the vascular portion of the eye, so as to produce a degree of inflammation. It is in this state that the eye becomes irritable, and the pupil contracted, in order to exclude the excess of light. For while the retina preserves its natural sensibility, the contractions and expansions of the iris in most instances go on unimpaired, and the eye appears as in perfect health.

Perhaps it may be thought that, if the disease be owing to an insensibility in the eye produced by the intensity of the sun's light, the patient ought also to be blind when removed to an obscure place during the day, seeing that in both cases the stimulus of light is withdrawn from the eye. This, however, we find, is not always the case. In explanation it may, perhaps, be alleged that the action of the sun's rays, for the *whole duration* of a long day, will more effectually contribute to produce that state of the organ which constitutes the disease than when they act only for a shorter period. The inference seems to be reasonable, but it would require to be confirmed by repeated observations.

Diseases of the brain, and such other causes as induce repletion in that organ, may also produce nyctalopia by injuring the optic nerves, either at their origin or in their course, and thereby so impeding their functions as to render them incapable of transmitting the slight impressions which are made on the retina by a faint light. The last stage of this form of the disease would constitute complete amaurosis.

The well-known sympathy which exists between the stomach and the organs of vision will readily account for nyctalopia appearing so often as an attendant on disorders of that viscus.

The varied illusions and other affections of vision familiar to persons subject to dyspeptic disorders, are analogous in many respects to this disease.

A very different and almost mechanical cause has been assigned for this disease by different authors, namely, a rigid and contracted state of the pupil, whereby a sufficient quantity of light is prevented from reaching the retina. It is very evident that such a state of the pupil might occasion the disease; and it seems to be sometimes observed, as several authors have mentioned its occurrence.*

Diagnosis.—Nyctalopia can scarcely be confounded with any other disease. Yet in a complaint of such frequent occurrence in the navy and army, and which affords such facilities for carrying into effect the schemes so often devised by seamen and soldiers to enable them to evade their duty, it would be an object of importance, if any sure diagnostic symptoms could be pointed out. The present state of our knowledge does not, however, enable us to do so with any thing like precision. If contracted or dilated pupil were an invariable concomitant, this would afford a ready mode of discrimination; but these states of the pupil have been rarely observed, even in cases of long duration. As there are no direct means by which the disease can be detected,† attention must, therefore, be paid to the character, habits, and conduct of the individual, and there are few instances in which investigation and experiment will not suffice for its discovery. For some remarks on this point, see the section on *Blindness*, in the article Feigned Diseases, vol. ii. p. 136.

Prognosis.—The prognosis in nyctalopia may generally be considered favourable; and, when proper means of treatment are speedily adopted, the disease is seldom protracted. It even frequently undergoes a spontaneous cure; and the instances are rare in which it is followed by any bad effects. It has also been occasionally removed by the supervention of diarrhœa, of hemorrhage from the nose, and of abscesses and eruptions about the head and face. In two of Dr. Forbes's cases, (Edin. Med. and Surg. Journ. vol. vii. p. 419,) epiphora succeeded; and according to Mr. Bampfield, (Medico-Chirurg. Trans. loc. cit. p. 40,) lippitude and myopism are sometimes consequent upon it. This author also states that total loss of sight has been known to ensue, and refers to Bontius in support of this opinion. But from the passage in Bontius, (De Medic. Indor. lib. iv. p. 32. Parisiis, 1645,) it is somewhat doubtful if the disease which is alluded to was nyctalopia. Some authors, however, have been of opinion, that the treatment of the disease is not always successful. According to Sennertus, (Opera Omn. tom. iii. par. iii. § ii. cap. 44, p. 227. Lugduni 1656,) and Ettmuller, (Opera Omnia Comp. Colleg. Pract. lib. ii. art. 1, p. 33. Lond. 1701,) it is seldom cured, and Boerhaave (De Morb. Ocul. § 158. Gottingæ, 1750) says, "nullum remedium scio, quod hoc malum tollere possit."

Treatment.—Physicians have very generally endeavoured to adapt their mode of treating a disease to the theory which they have formed respecting its cause. This remark has been fully verified in the treatment of nyctalopia. The *humoral* pathologists, who supposed the disease to depend upon a superabundance, thickening, or congestion of the humours, had recourse to such remedies as they considered adapted for diminishing, altering, or evacuating the various humours of the body in general, and of the eyes in particular. For these purposes they recommend *attenuant diet* and bleeding, both general and local. They employed also purgatives, particularly those which they considered as suitable to diseases of the eyes —"oculis appropriata." Nor were other evacuants omitted—*sternutatoria*, *pituitaria*, and the like. Various local applications were also made use of, such as collyria, unguents, and powders, elaborately compounded with all the superfluous science, and multifarious ingredients resorted to in ancient pharmacy. Some things were recommended as remedies on principles evidently the most absurd. Thus, according to Galen and Celsus, *hieracion* was advised, because "accipitres aiunt scalpendo eam, succoque oculos tingendo, obscuritati visûs mederi; ob idque vocant hieracion." (Foresti Opera Omnia, lib. xi. obs. 38. Francof. 1634.) *Euphrasia* was thought good for the sight, from an imaginary resemblance between the spots on its petals, and the eyes. Many other equally fanciful examples might be adduced, but it may suffice to quote the following from an author of high celebrity:—"Capras negant lippire, quoniam eæ quasdam herbas edant: item dorcadas: et ob id fimum earum cera circumdatum nova luna devorare jubent. Et quoniam

noctu æque quoque cernant, sanguine hircino sanari lusciosos putant, nyctalopas a Græcis dictos." (C. Plinii Secund. Natur. Hist. tom. iv. lib. xxviii. § xlvii. p. 616. Parisiis 1685.) Thus it would appear that, from the visual faculties possessed by those animals, of seeing by night as well as by day, the employment of their livers in the cure of nyctalopia took its rise. This is a remedy, the astonishing powers of which have been extolled, both in ancient and modern times, and in countries the most widely separated, with a confidence truly inexplicable. The livers of various animals were occasionally employed; but those of he-goats, bullocks, and of sheep, were preferred. Sometimes the vapour of the heated liver was applied to the eyes; at other times the viscus itself was given to the patient to eat; in both cases frequently after it had undergone the most complicated preparations, particularly with various stimulating substances. It is difficult to believe in the production of a cure by such means; and yet it would require no small degree of incredulity to set aside altogether the evidence which has been adduced in favour of these remedies.

A recent German writer has given a remarkable instance of the apparent power of this hepatic treatment of nyctalopia. As the account is altogether curious, we give the narrative at length. The author, Dr. Edward Meissner,* informs us that in a small town in Podolia, on the banks of the Bug, having a population of about 2000, some weeks before Easter, in the year 1816, he met with more than a hundred cases of nyctalopia. "I discovered this," he says, "accidentally one evening, when my surgeon, a Jew, came home hurt, having been overturned by the man who drove him, and who had suddenly become blind as the sun set. Upon inquiring why none of these people were brought to me, I was told that they very well knew how to cure themselves, and would do so as soon as they were at liberty to use the means. It was then the time of fast, when those of the Greek church use no animal food, but live chiefly on bread and grits prepared with oil. I was assured that at the same period every year a great many people were seized with nyctalopia, but that when Easter came they ate the liver of a black cock or black swine, and were cured in a few days. I had ten of these people brought to me both during the day and in the twilight, but could perceive nothing particular in their eyes, except a great immobility of pupil. In other respects they were all in perfect health, and would submit to no other kind of treatment, assuring me that they knew they would be quite free from their malady within fourteen days without my medicines. On Easter day they began to eat liver *and other animal food.* Two of those I had examined, on the third day saw as well as ever; and all were completely cured by the following Sunday."

The writer of this article has repeatedly seen a cure *apparently* produced by fumigating the eyes with the vapour of bullock's liver. The disease occurred in persons who were in some degree affected with scurvy; and various measures had been employed for its removal without benefit. The patients themselves had recourse to the bullock's liver, and declared that one or two fumigations entirely cured their complaint.

We are as yet but little acquainted with *nervous* diseases, and are too well aware of their intermitting nature to put implicit faith in the efficacy of such a remedy. The disease in these, as in many other instances, may have undergone a spontaneous cure; or it may have owed its removal to some cause which was unknown or unobserved. It must be acknowledged that the *minute* history of nyctalopia is still very imperfect.

[Besides, it is important to bear in mind, that the disease often gets well spontaneously. Dr. Wharton, of the United States Army, cured several cases by simply excluding light. The cure was effected in from 24 to 60 hours. (Lawrence, *Op. cit.* p. 540.)]

Could any remedial exhalations have proceeded from the broiling liver? or did the application of heat alone suffice to excite the torpid retina into healthy action?

In the case of the Podolians above mentioned, it is obvious that we are entitled to attribute the case as much, *at least*, to the general change in their diet, as to the specific influence of the black pig's or cock's liver.

Viewing nyctalopia in the light of a more rational pathology, it is hardly necessary to say that, to give hopes of successful treatment, regard must in all cases be had to the nature of the causes which immediately induce the disease. If it appear to proceed from fulness of blood in the head, or any affection of the brain, bleeding and other means, tending to remove such a condition, are of obvious propriety. If derangement of the digestive organs give rise to the complaint, emetics, purgatives, or such other remedies as are suitable for removing the primary disease, must be employed; and when scurvy, or any other general affection of the system prevails, the appropriate means for its removal will be adopted as the first step in the treatment; and after the chief predisposing cause has been subdued, attention will then be paid to the treatment of the local affection. Nyctalopia, however, is often unaccompanied by any specific or formal disease, and appears to depend upon general and local debility. In such cases our efforts will be directed to restore the general strength of the body, and more particularly of the eyes; and this will be most readily accomplished by avoiding the exciting causes, and by employing tonics and stimulants, both general and local. Dr. Guthrie informs us that, in a week or fourteen days, the disease "is cured by the use of a bitter tonic infusion,† although the patient continue his daily hard labour, providing he sleeps as at other seasons during the night." Although the complaint may certainly be in this way removed, yet a cure is induced still more speedily by the application of blisters to the parts immediately adjacent to the local affection. They stimulate the eyes more effectually than general remedies do; and as during their application the patient is

* Bemerkungen aus dem Taschenbuche eines Arzes wahrend einer Reise von Odessa, &c. *Halle*, 1819. See also Encyclopädisches Wörterbuch. B. V. p. 388. *Berlin*, 830.

† Made, he believes, from the "Centaurea Cyanus" of Linnæus. Edin. Med. Comment. loc. cit. p. 288.

usually allowed to go to rest at night, they constitute an important part of the remedial process in the case of seamen or others subject to night-watching. The merit of more particularly recommending blisters, and determining their efficacy in the cure of this disease, belongs to Mr. Bampfield, though the remedy is not new, as they are known to have been employed from a remote period. His words are, "A succession of blisters to the temples, of the size of a crown or a half-crown piece, applied tolerably close to the external canthus of the eye, has succeeded in every case of idiopathic hemeralopia which I have seen. Under their application, the retina appeared to regain its irritability, and sensibility to impressions from light, in the same gradual manner as it was deprived of it." (Medico-Chirurg. Transactions, loc. cit. p. 47.) In his practice, one or two applications were often sufficient to remove the complaint; but the third, fourth, or fifth generally produced a complete recovery. The instances are but few in which there was occasion for a greater number of blisters; or by keeping them open, the cure was generally completed within a fortnight. During the time in which they are applied, exposure to a bright light ought to be carefully avoided; and the patient should be allowed a sufficient time for sleep. The eyes may also be frequently bathed with cold water, or some tonic or astringent lotion.

Besides blisters, other local stimulants have been employed, particularly the vapour of ammonia; frequently, however, with indifferent success. The stimulus of electricity has been used with advantage; and, reasoning from analogy, it might be expected to prove highly beneficial, as also galvanism.

It may be proper just to notice in this place the analogous but reverse lesion of vision, termed **Hemeralopia** by those who give the name of nyctalopia to the affection of which we have been treating, in which the patient is blind during the day, but sees comparatively well at night. This disease is noticed by Hippocrates, and many other authors, both ancient and modern; but as it has never fallen under our own observation, except as a mere symptom of ocular inflammation, and as its occurrence as an idiopathic affection is, we are convinced, extremely rare, we deem it unnecessary to give any particular account of it. It may no doubt arise from such local affection of the retina of an organic though unknown kind, as to entitle it to be considered idiopathic; the relative excess of light producing here the same effect as its relative deficiency did in nyctalopia. When, however, not the immediate consequence of inflammation of the eye, it has commonly been observed as the temporary attendant of hysteria, or as a symptom of worms, or other irritation sympathetically affecting the brain generally, or the optic nerves in particular. It therefore deserves no separate consideration in this work as a distinct disease.

JAMES GRANT.

OBESITY.—This term, from the Latin obesitas, *fatness*, *corpulency*, its synonym *polysarcia*, from πόλυς, *much*, and σάρξ, *flesh*, and many others of similar import, are used to signify an excessive development of fat in the body.

Of all animal solids, fat may be named as that which may vary most in quantity without material infringement on the health. Thus we see persons in very various degrees of fatness or leanness enjoying the best health; and even the same individual, under different circumstances of diet and regimen, may become fat or lean without and corresponding change in the well-being of his body. There is, nevertheless, in most individuals, a certain degree of stoutness which best comports with that regular balance of functions which constitutes perfect and permanent health. This degree in some persons may not rise above leanness; and in these even a moderate degree of embonpoint is often a precursor or a sign of disorder; whilst in many, a fulness and rotundity of person is natural, and not only consistent with, but indicative of perfect health. This statement shows the impossibility of defining absolutely what degree of obesity is to be considered as morbid, although in its excessive degrees it is unquestionably a disease and a cause of disease. Cullen describes obesity as morbid "when it renders persons from a difficult respiration uneasy in themselves, and from the inability of exercise, unfit for discharging the duties of life to others." (First Lines, ed. by Cullen and Gregory, vol. ii. p. 208.)

Fat may be developed in excess at any period of life, but some ages are much more disposed to obesity than others; and these are infancy and maturity. Infants at the breast sometimes acquire a prodigious size from the deposition of fat. Usually this is chiefly confined to the subcutaneous tissue, and very little affects either the cavities or the interstices of the muscles; but when such children are affected with somnolency and a shortness of breath, which renders sucking difficult and movement laborious, the accumulation of fat may be supposed to be more general, and to oppress by its mass the organs of respiration, circulation, and motion. This condition is almost uniformly caused by an excess of nourishment, and is not unusually attended by a torpidity of the bowels. Fat infants are generally good-tempered; and it is difficult to say whether this be a cause or a consequence of their fatness; but a fretful disposition is generally consorted with an irritability of the secretory organs, which is opposed to any superfluous growth. The obesity of infancy generally diminishes after the second year; and it is not unusual to see the subjects of it become as thin as other children before the age of puberty. The demands of other solids of the body, which the increasing exercise at this period produces, operate against the superfluous deposition of fat; and the fuller development and greater activity of the mental faculties perhaps have a similar effect. In some of the most remarkable cases on record, however, the inordinate development of fat continued and increased regularly from infancy upwards. A German girl, who was exhibited some years ago in Paris on account of her prodigious size, at her birth weighed 13 lbs.; at six months, 42 lbs.; and 150 lbs. at four years. She showed great physical strength as well as size, for when six years old she was able to carry her mother. She ate much milky food in her childhood, and afterwards drank large quantities of tea, but did not eat more than another person. She menstruated at the age of nine years, and always

enjoyed very good health, being active and lively in her disposition. At the age of twenty she weighed 450 lbs., she then could carry in each hand a weight of 250 lbs., and could walk for an hour without requiring rest, but her breathing was short on going up stairs. Her arms measured eighteen inches (French) in circumference; and the fat formed annular rolls, as in the thighs of very fat infants. (Dict. de Médecine, art. *Polysarcie.*) Many similar cases are related in Mr. Wadd's amusing monograph on *Corpulency*, from which we extract the following.

Isaac Butterfield, born at Heightley, near Leeds, Feb. 20, 1781; in November 1782 he measured three feet in height, thirteen inches round the arm, two feet two inches round the thigh, sixteen inches across the shoulders, and weighed near one hundred weight. He died Feb. 1, 1783.

A child named Thomas Hills Everitt was publicly exhibited in London in 1780. He was not remarkably large when born, but began to increase rapidly when six weeks old, until his death, which happened at eighteen months. At eleven months he measured three feet nine inches in height; two feet six inches round the breast; three feet one inch round the loins; one foot ten inches round the thigh; fourteen inches round the leg; eleven inches and a half round the arm, and nine inches round the wrist.

Mary Tate, aged twelve years, the daughter of a publican in Cambridge, and one of twins, weighed thirteen stone; the other child died at two years. When Mary was born, she was not larger than is usual, but began to increase at five years; and at six she was publicly exhibited. Her parents were corpulent. She was attacked with a fever which prevailed at Cambridge a few months before her exhibition, and recovered without any apparent diminution of size. Mr. Wadd has collected a great number of other instances of obesity, but as they are merely named, with scarcely any particulars of their history, they are objects of curiosity rather than of medical interest. In most of the well-recorded instances of obesity in early life, there has been an uncommon development of muscular strength; and in this respect the obesity of childhood differs from that supervening in after-life.

[A girl, said to be only ten years old, called the "Ohio giantess," was lately (1844,) exhibited in Philadelphia, who was said to weigh 265 pounds; and the case of a girl is detailed, who weighed 256 pounds, when only four years old. (*Philosophical Transactions*, No. 185.) Dr. Elliotson (*Human Physiology*, Lond. 1841, part 1, 301,) saw a female child, but a year old, who weighed sixty pounds. In these cases the specific gravity of the body may be much less than that of water. It is said that there was a fat lighter-man on the Thames who had fallen overboard repeatedly, without any farther inconvenience than that of a good ducking; "since, though he knew nothing whatever of swimming, he always continued to flounder about like a firkin of butter, till he was picked up." (Fletcher, *Rudiments of Physiology*, part i. p. 71, Edinb. 1835; and the writer's *Human Physiology*, 5th edit. ii. 239: Philad. 1844.) The Lowell Advertiser, of this very date, (Sept. 1844,) states that a coloured girl, aged fourteen years, a native of Nassau, N. Y., had died in that city, weighing *five hundred* pounds.]

A remarkable case of obesity in early age was lately brought before the Royal Institution by Mr. Pettigrew. It was a boy, twelve years of age, who weighed 198 lbs. The great increase of his bulk took place after confinement, in consequence of a fracture of one of his limbs. His health is now good, and his habits, appetites, and mental development present nothing uncommon for a boy of his age. He is not deficient in activity, but he says that he cannot lift more than five stone weight.

After the completion of longitudinal growth the adipose membrane again receives the overflow of the nourishment of the body; this is less remarkable in males than in females, in whom the nutrient function is naturally more active. In both sexes, however, the irritation of the generative organs at the early epoch of maturity seems to have a remarkable effect in diminishing the plumpness of the body; and the absence of this influence in eunuchs produces the sleek smooth surface so remarkable in their bodies, in which the inequalities of bone and muscle are buried in a bed of fat. It is a familiar fact that some of the lower animals fatten much more readily after the removal of the testicles or ovaries. It is perhaps partly in connection with this circumstance, and partly from the abatement of other excitements of youth, that obesity more frequently and more decidedly shows itself as maturity advances; and it is after the fortieth or forty-fifth year that it attains its greatest degrees. The diminished mobility of both mind and body which is perceptible at this age, and the greater inveteracy of habits of living, render corpulency then a much more serious evil than in earlier life; for these circumstances, unless steadily and vigorously counteracted, will infallibly increase it in a degree that must abridge life by encroaching on the functions of various internal organs, and laying the foundation of fatal diseases. This we shall see sufficiently explained in the situations which fatty accumulations occupy at these ages. Besides the thick bed of fat in the subcutaneous tissue, and in the interstices of the muscles, the mediastinum, the pericardium, the mesentery, and the omentum, become the seats of prodigious adipose depositions. Such subjects, besides a largeness and rotundity of body and limb generally, have a protuberant abdomen, and the loose texture in the axillæ, under the chin, and about the mammæ of women, becomes in like manner distended with fat. The effect of these accumulations is mechanically to oppress the adjoining organs; hence, shortness of breathing and asthma, weak or irregular action of the heart and palpitation, an oppression and consequent disorder of the digestive apparatus, inability of movement, obstructions to a free circulation of the blood, and dropsical effusions. The cavity of the head is the only one which escapes the deposition of fat; and this exemption exposes its contents to a still greater evil. The various obstructions to the circulation, and the increased pressure to which the mass of fat throughout the body subjects it, produce a determination of blood to the head, and congestion; whence arise somnolency, torpor of the mental

and animal functions, and sometimes apoplexy and sudden death.

We have hitherto considered obesity as a simple hypertrophy, but there is reason to believe that in many cases the fatty substance encroaches on the nutrition of other structures. In very fat subjects, both in man and in the lower animals, the fibres of the muscles are often interspersed with depositions of fat, sometimes to such a degree that the latter constitutes the greater part of what once was muscle, and the remaining fibres are commonly softer and paler than is natural. All the muscles are liable to this change, and the heart among the rest; the consequence necessarily is a diminution of their contractile power. We have seen the heart thus more than half converted into fat; the adipose tissue of the base and surface having encroached on the muscular fibres, so that at the base and along a great part of the wall of the right ventricle, and at the septum of the ventricles, these fibres only formed a thin stratum irregularly terminating in the adipose tissue. Laennec describes this state of the heart, and says that "the fatter the heart is, the thinner in general are its walls; and on cutting into them the scalpel seems to reach the cavity without encountering almost any muscular substance, the columnæ carnæ appearing merely as if bound together by the internal lining membrane." (Dr. Forbes's Trans. p. 637.) He distinguishes it from fatty degeneration by the marked difference between the muscular fibre and the fat, the latter seeming rather to have superseded the fibres than to have been formed in them. The effects of this change must be unquestionably to render the action of the heart weak, and the circulation languid and inefficient; and some of the instances of the sudden death of fat persons may reasonably be ascribed to a rupture of the organ in this weakened state. M. Bertin describes a case of the rupture of a prodigiously fat heart. But the mere diminution of power in the heart, and its oppression by a load of fat, without any rupture, seem to have caused death in some cases. Dr. Brian Higgins of Dublin, the first discoverer of equivalents in chemistry, appears to have died from this cause; and there are many similar examples on record. These forms of obesity must have a tendency to increase; for as fat is deposited in and around the muscles, they will be less disposed to that habit of exercise on which their development mainly depends, whilst obesity and its causes will increase together.

Without dilating this article with cases of extraordinary obesity, we may state generally that the fat, which is computed to constitute an average of from 1-10th to 1-15th of the weight of the body in persons of ordinary degrees of stoutness, in extreme cases amounts to 4-5ths; and the absolute weight, which runs commonly from 10 to 14 stone (14 lbs.), has been known in remarkable cases of this disease to reach to from 30 to 50 stone. Mr. Lambert, of Leicester, who is always placed at the head of the list, weighed 52 stone 11 lbs. There is detailed in the twelfth volume of Corvisart's *Journal de Médecine et de Chirurgie*, an interesting account of a case of obesity by M Dupuytren, with a full description of the tissues affected and the proportion of fat in various parts of the body: an extract from this has already been given in the article Hypertrophy, and it is therefore unnecessary to repeat it here.

Obesity is sometimes partial: and it has its seat in no part more frequently than in the omentum, which has been known to increase to the weight of 20 or 30 lbs. This gives the appearance of what is vulgarly called a pot-belly. The mediastinum is likewise occasionally filled with fat without a corresponding obesity of the body; and the double chin often occurs as a partial obesity. The mammæ, abdominal paricles, and nates of women are likewise sometimes the seats of fatty enlargements; the latter are so to a ludicrous degree in the Bosjesman Hottentots.

Pathology.—Fat is an oily matter contained in minute vesicles which are agglomerated together in masses in the cellular tissue of various parts of the body. Whether there is a peculiar adipose tissue, or whether the fat is deposited in the common cellular structure, is a matter of dispute amongst anatomists. Dr. W. Hunter described the adipose tissue as distinct, and as consisting of cells which do not communicate with one another. He grounds his opinion on the following facts. The parts where fat most commonly accumulates are not those which are most subject to œdematous and emphysematous swellings, nor do the forms of parts increased by fat, and of those whose cellular tissue is distended by serum, resemble each other. Adipose accumulations do not pit on pressure, or gravitate towards the most dependent part, as anasarcous effusions do: the scrotum, so commonly the seat of the latter, is scarcely ever affected with fatty enlargement. W. Hunter's opinions have been adopted by Monro, Mascagni, Bichat, and Beclard. Haller, Wolff, Hensinger, Magendie, and Meckel deny the existence of a peculiar adipose tissue, and consider that fat is merely deposited in globules in the cellular structure. Meckel supposes the fat to be a solid, manifesting itself in globules, which make cells for themselves in the mucous tissue, in which he asserts there is naturally no cellular division or communication. A minute examination of human fat does not confirm this latter opinion, for it traces its globular form to the presence of an investing membrane, while the contained oil is liquid or solid, and the animal temperature according as elain or the stearin prevails in it, which varies in different parts of the body. We are, therefore, disposed to retain Dr. Hunter's view, which is confirmed by the distinct and characteristic appearance which the adipose substance presents when surrounded by serous infiltration of the cellular tissue.

There has been an equal discrepancy of opinion as to the place of the formation of fat. Haller and Magendie consider it as a simple exhalation from the blood. Dr. W. Hunter ranks it as a secretion elaborated by the specific tissue in which it is found; whilst Sir E. Home has framed a curious hypothesis, that it is formed from the fæcal part of the food in the colon, whence it is taken up by the blood-vessels, and deposited in different parts of the body. Almost the only argument urged in favour of this last notion is a supposed resemblance between the retention of fæces in the colon, and certain cases in which de

cayed animal matter is converted into adipocire: this resemblance is very slender and distant; and if Sir E. Home has proved that an oily matter is sometimes present in the fæces, he has failed to prove that it is either formed there, or conveyed thence into the system; whilst on the other hand there are on record cases which prove that fat may be formed and deposited in the body without any aid from the colon. Thus the subjects of artificial anus have been known to get fat, although no fæces passed through the large intestines. (See Dr. Mackeever on Laceration of the Uterus, p. 48, 1824.)

The question whether fat exists ready formed in the blood, or is only elaborated at the point in which it is deposited, is much of the same nature as that respecting other secretions, such as urea, bile, mucus, &c. Commonly none of these are detected in the blood, but under some circumstances they may each be found to exist there; and the presence of fat giving a milky aspect to the serum* is not so uncommon as to exclude the probability that it always exists, but in proportions too small to be readily appreciated unless circumstances lead to its accumulation. And we have the positive testimony of Drs. Christison and Babington, and more recently of M. Lecanu, that there is always fatty matter in the blood, according to the latter chemist, in ordinary cases amounting to from three and a half to six and a half in a thousand parts. (Journ. de Pharm. Sept. and Oct. 1831.) These facts, coupled with the well-known presence of oily matter in the chyle, remove much of the difficulty of explaining the rapid accumulation of fat in the body under some circumstances, and its still more speedy reduction in others. These changes, if not the result of simple exhalation and absorption, are obviously more nearly allied to them than they were formerly considered to be; and although the secernent power of vessels is undoubtedly concerned in the deposition of fat, we must not overlook the cohesive quality of this substance, by virtue of which it agglomerates to matter of its own kind, whilst watery liquids have but little affinity for it. Hence we can perceive why blood surcharged with fatty matter from the chyle promptly deposits it, especially where adipose substance already exists; whilst for its removal there must be an augmented energy of the absorbent function. This view, which is but an hypothetical one, would assign the chylopoietic viscera as the probable seat of the formation of fat, although there may be reason to believe that it becomes modified and perfected in its progress through the circulation.

Another conjecture has been proposed by Dr. Bostock, that fat is formed like other secretions from the blood; and its production, by removing a superfluity of hydrogen, is a means of maintaining a uniformity in the composition of the circulating mass. The kidneys are the emunctories of azote, and the lungs of carbon, whilst fat, the prevailing ingredient of which is hydrogen, may maintain the balance by carrying off the superfluous hydrogen. If this were the mode of its production, the excessive development of fat ought to be accompanied by an unusually copious secretion of urea by the kidneys, a circumstance not, as far as we know, attributed to cases of obesity.† Of the excretions, that of the liver bears the nearest analogy to fatty matter; and this fact suggests a question whether an obese diathesis may not be sometimes connected with a comparative torpidity of this viscus.

Causes.—These may, as usual, be divided into predisposing and occasional. The predisposing, as consisting in a peculiar habit or temperament of body, is frequently hereditary. At the first glance, we may be led to say that the predisposing cause is the most powerful, inasmuch as no mode of diet and regimen will succeed in making some persons fat, whilst others increase to a great size, without, in these particulars, exceeding the bounds of moderation. A more comprehensive survey, however, of the symptoms in different cases, suggests that the constitutional cause is not always of the same nature, and that therefore it has a varying share in the production of morbid obesity. A full diet, especially abounding in oily, carneous, saccharine, and farinaceous matter, will seldom fail to fatten a person naturally disposed to corpulency; and if to this, rest of body and mind be added, this effect is almost certain. Some individuals, having a strong constitution and good general health, require these to make them fat, and become so only in proportion as they indulge in them. These persons, in whom the predisposing and exciting causes may be said to be nearly balanced, constitute a large proportion of the cases of moderate obesity that are commonly met with. In them the circulation and other functions are effective and regular, the secretions free, and the bodily and mental powers little embarrassed. Their corpulency is merely an overflow of health, the deposition of fat being the outlet by which the blood-vessels deliver themselves from impending plethora, and is accompanied by an increase rather than a diminution of other solids. This form we would denominate *sthenic* obesity. A preponderance of the same predisposing cause, the hypertrophic diathesis, gives a more marked form of the disease, and constitutes the greater number of those cases of uncommon size and strength which are frequently shown about the country. When this form of obesity becomes much pronounced, by the embarrassment which it causes in the functions, it tends to pass into the second variety of the disease, which we would term *asthenic*.

In asthenic obesity, the predisposition is still

* We once saw this milky appearance of the serum very remarkable in the blood of a corpulent patient suffering under an attack of pneumonia; she had been largely bled previously.

† We cannot omit the opportunity to express here our conviction, that a more frequent and habitual attention to the state and composition of the excretions would greatly enlarge our knowledge of the pathology of diseases. The interesting study of animal chemistry has established, to a certain degree, that the great excretory organs, the liver, the lungs, and the kidneys, act as balancing forces, which keep the blood of a uniform nature; and it must, therefore, be obvious, that the inordinate or imperfect action of any of these would lead to a more or less disordered state of this fluid, which must necessarily react on the functions at large. Without advocating an absolutely humoral system of pathology, we cannot but view a disordered state of the fluids as an important link in the concatenation of diseased action, and as a main object of therapeutic efforts. For a clear insight into this subject, much patient and well-directed research is required; and had we a few more such inquirers as Dr. Prout, we might sanguinely look forward to the attainment of this point.

more strong, and probably consists of a greater number of constitutional causes. This predisposition is frequently hereditary, and is commonly allied with a leucophlegmatic temperament, a soft, languid pulse, defective excretions, and a low irritability of the body. There is in such individuals a sufficient activity of the first part of the digestive process; but a somnolent disposition, often present for some hours after meals, indicates the admixture of chyle in the circulation, and a tardiness in its assimilation. The chyle thus supplied probably abounds more in fatty particles than in albuminous globules. Until, therefore, the former are deposited from the circulating mass in the adipose membrane, the blood does not recover its natural and most healthy constitution. There is good reason to believe that naturally this adipose matter is always at the command of the absorbent functions, and that, in case of the excretions being augmented in a greater ratio than the supply of nutriment, it is taken into the circulating mass to make up for the waste. In a person of sanguine temperament, the demand on the adipose membrane equals the supply: such an individual makes blood fast, and suffers from plethora before there is any considerable increase of fat in the body. A person of spare habit, again, is liable to neither form of hypertrophy; as either the incapacity of his digestive organs, or the activity of his excretions, preclude all superfluous accumulation. In asthenic obesity, on the other hand, there is a defect in the assimilatory process by which the oily matter is made available to supply the excretions of the body; and this defect may be either in the absorbent function, or in that action by which the matters excreted are formed; but it is most probable that the same defect of tone which manifests itself in the state of the body generally, extends to both these functions. Hence asthenic obesity resembles atonic dropsy, in which it not unfrequently terminates: it occurs towards the later periods of life, and in persons whose constitutions have been weakened by various excesses. It is not unfrequently the accompaniment of chronic disease of the liver, and more rarely of the stomach; and is sometimes a symptom of a chlorotic state in young women. It is in this form of obesity that the muscles become paler, lose their substance, and are displaced by depositions of fat.

We have already stated that good living and a life of ease are the most efficient occasional causes of obesity; this is universally acknowledged; and Dr. Arbuthnot says, "you may see an army of 40,000 soldiers without a fat man; and I dare affirm that by plenty and rest, twenty out of the forty shall grow fat." The portly appearance of butchers, landlords of inns, and butlers, is obviously referable to their good living and moderate exercise.

With respect to the quality of food which is most fattening, much variety is seen; either animal or vegetable diet being capable of producing the most marked effect, if taken in sufficient quantities. Thus the negroes of the West Indies, and the Chinese slaves, sometimes acquire an enormous size during the sugar season by drinking the cane-juice; and it was remarked by Galen, that the keepers of vineyards, who live on nothing but figs and grapes, become fat. The ladies of Tunis and Tripoli are fattened, to please the tastes of their lords, with farinaceous food, and a seed called *drough*. "Among the Asiatics there is a sect of Brahmins who pride themselves on their extreme corpulency. Their diet consists of farinaceous vegetables, milk, sugar, sweetmeats, and ghee. They look upon corpulency as a proof of opulence; and many arrive at a great degree of obesity without tasting anything that has ever lived." (Wadd's Remarks, &c. p. 80.)

Malt liquor, consisting of a saccharine and feculent infusion, rendered readily digestible by the stimulant and stomachic properties of the bitter and spirit with which it is combined, is highly nutritious, and some of the most remarkable subjects of obesity have been addicted to excessive indulgence in ale or porter. The following case is related by Mr. Wadd.

"A few years ago a man of about forty years of age hired himself as a labourer in one of the most considerable ale-breweries in the city. At this time he was a personable man; stout, active, and not fatter than a moderate-sized man in high health should be. His chief occupation was to superintend the working of the new beer, and occasionally to sit up at night to watch the sweet wort; an employment not requiring either activity or labour: of course at these times he had an opportunity of tasting the liquor, of which it appears he always availed himself: besides this, he had constant access to new beer. Thus leading a quiet inactive life, in a short time he became of such an unwieldy size as to be unable to move about, and was too big to pass up the brewhouse staircase; if by any accident he fell down, he was unable to get up again without help. The integuments of his face hung down to the shoulders and breast: the fat was not confined to any particular part, but diffused over the whole of his body, arms, legs, &c. making his appearance such as to attract the attention of all who saw him. He left this service to go into the country, being a burthen to himself, and totally useless to his employers. About two years afterwards he called upon his old masters in a very different shape to that already described, being reduced in size nearly one half, and weighing little more than ten stone. The account which he gave of himself was, that as soon as he had quitted the brewhouse he went into Bedfordshire, where having soon spent the money he had earned, and being unable to work, he was brought into such a state of poverty as to be scarcely able to obtain the sustenance of life, often being a whole day without food; that he drank very little, and that was generally water. By this mode of living he began to diminish in size, so as to be able to walk about with tolerable ease. He then engaged himself to a farmer, with whom he staid a considerable time, and in the latter part of his service he was able to go through very hard labour, being sometimes in the field ploughing and following various agricultural concerns for a whole day, with no other food than a small pittance of bread and cheese. This was the history he gave of the means by which this extraordinary change was brought about. He added, his health had never been so good as it then was"

In another case, from the same writer, more of the asthenic kind, the subject, a woman who died suddenly at the age of forty-four, weighing twenty-three stone, had subsisted chiefly on vegetables and pastry, and drank large quantities of milk and water, consuming above a gallon in the course of each night. She was totally incapable of rising from her bed, and required three strong men to place her in her chair.

While these cases show that the quantity more than the quality of nutritious aliment supplies the disposition to obesity where it exists, it is at the same time certain that fat meats, butter, milk, the saccharine, the finer farinaceous, and the oily vegetable substances, with malt liquors for drink, are the most fattening kinds of food; and varied combinations of these are more effectual to this end, inasmuch as they are more inviting to the appetite, and more manageable, even in large quantities, by the digestive organs, than simple substances, however nutritious.

Besides food, there are other circumstances which contribute greatly to the production of obesity. Absolute rest is less powerful than some kinds of moderate exercise, as it can seldom be indulged in without such an interruption to health as would prevent the fattening process. The obesity which ensues on absolute rest is generally more of the asthenic kind. There is no mode of living that seems to dispose more to obesity than that of a regularly employed coachman. The gentle exercise and free exposure to the open air which their occupation entails upon them, gives a good appetite and easy digestion; and while they seldom fail to indulge these, they are rarely called upon for those exertions of the lower extremities, or of the whole frame, that reduce the body by a general increase of the excretions.

Mental repose, both of the powers and passions, has been considered a great promoter of obesity. We think, however, that the sluggish minds and easy tempers of fat people are as often the effect of the phlegmatic constitution which disposes to obesity, as a cause of this state. They are frequently accompaniments of asthenic obesity; and a somnolent inactivity of the mind, as of the body, may be the effect of an advanced state of any kind of corpulency: but the case of David Hume, the historian, who became very fat during his intellectual labours, and that of Napoleon under the most powerful excitements of passion and mental energy, and many others which we could cite, prove that fat and stupidity are not such inseparable companions as Lord Chesterfield represented them.

The national differences which are observable in the disposition to obesity are probably referable more to the temperament, diet, and habits of the people, than to any peculiarities in climate. It has been stated that obesity sometimes commences after convalescence from a fever, or after a course of mercury; and all that can be said in explanation is, that these influences seem to produce in various respects a change in the constitutional diathesis, as other morbid tendencies, not pre-existent, are occasionally developed by the same causes. We have known a partial accumulation of fat succeed to repeated attacks of erysipelas in he part; this bears more analogy to common nypertrophy.

[In the view of Liebig, (*Animal Chemistry*, Webster's edit. p. 85, Cambridge, Mass. 1842,) the abnormous condition, which causes the undue deposition of fat in the animal body, depends on a disproportion between the quantity of carbon in the food, and that of the oxygen absorbed by the skin and lungs. In the normal condition, the quantity of carbon given out is exactly equal to that which is taken in with the food, and the body experiences no increase of weight from the accumulation of substances containing much carbon and no azote; but if the supply of highly carbonized food be increased, the normal state can only be preserved by exercise and labour, through which the waste of the body is increased, and the supply of oxygen accumulated in the same proportion. The production of fat, Liebig maintains, is always a consequence of a deficient supply of oxygen, for oxygen is absolutely indispensable for the dissipation of the excess of carbon in the food. "This excess of carbon, deposited in the form of fat, is never seen in the Bedouin or in the Arab of the desert, who exhibits to the traveller with pride his lean, muscular, sinewy limbs, altogether free from fat; but in prisons and jails it appears as a puffiness in the inmates, fed, as they are, on a poor scanty diet; it appears in the sedentary females of oriental countries; and finally it is produced under the well-known conditions of the fattening of domestic animals."

Whether the view of Liebig be admitted or not, it is certain that the circumstances which favour obesity are absence of activity and of excitement of all kinds.]

Treatment.—It is sufficiently obvious from all that has preceded, that diet and regimen constitute the most effectual means of cure in this disease; and Dr. Radcliffe's pithy motto, "to keep the eyes open and the mouth shut," promises more benefit than any medicinal prescription. The following cases, which are only specimens out of a very long list, will illustrate the efficacy and safety of this plan, as well as its modes of application, better than mere general rules.

Mr. Wood (the miller of Billericay, whose case is related by Sir George Baker in the Medical Transactions of the College of Physicians,) at his forty-fourth year had attained such a size that he was a burthen to himself, and incapable of performing common acts of exertion. At the suggestion of the rector of his parish, he resolved to follow the example of Cornaro in a life of abstemiousness. He had been accustomed to indulge in large quantities of ale and animal food, with an unsparing proportion of fat. These he left off gradually, and substituted puddings of flour and milk; and at last, one made of sea-biscuit, eaten twice only in the day, was his only food. He first substituted water for beer, but afterwards brought himself to do without any liquid. By this plan he reduced himself ten or eleven stone, and was "metamorphosed from a monster to a person of moderate size; from the condition of an unhealthy decrepid old man to perfect health and the vigour and activity of youth."

A country tradesman, aged about thirty, of a short stature, and naturally of a fresh sanguine complexion and very fat, applied to Dr. Fothergill for assistance. He complained of perpetual drow-

siness and inactivity; his countenance was almost livid, and such a degree of somnolency attended him that he could scarcely keep awake whilst he described his situation. Dr. Fothergill advised him immediately to quit all animal food, to live solely on vegetables and every thing prepared from them, allowed him a glass of wine and a little beer occasionally, but chiefly confined him to water. He pursued this plan very scrupulously, lost his redundant fat, and grew as active as usual in about six months. Dr. Fothergill recommended a perseverance for a few months longer, then to allow himself light animal food once or twice a week, and gradually to fall into his usual way of living. He grew well, and continued so.

A young unmarried woman, about twenty-three years of age, of low stature and very fat, consulted the same physician, on account of great difficulty of breathing, somnolency, and incapacity for any exercise. It was a hardship to her to be obliged to go up stairs, and at last to cross the floor of her apartment. It seemed to Dr. Fothergill that mere obesity was her principal malady; indeed she had no other complaint but such as might be accounted for from this supposition. She was ordered to pursue a vegetable diet, and in the summer to drink the waters at Scarborough. She conformed to these directions, became more agile, less sleepy, less averse to exercise: she walked up stairs at Scarborough from the Spa, a task of no little difficulty to people much less encumbered. A continuance of the same diet was urged: she was dissuaded from it by her friends, and died of fat in the twenty-seventh year of her age. (Med. Obs. and Inq.)

A gentleman of great respectability in the mercantile world, who weighed thirty-two stone nine pounds, put himself upon a strict diet of four ounces of animal food, six ounces of bread, and two pounds of liquid, in twenty-four hours. In one week he lost thirty pounds weight, and in six months he was diminished the astonishing quantity of one hundred and thirty-four pounds. His health and spirits were much improved; and considering his remaining size of twenty-three stone, he was very active. (Wadd, p. 82.)

Mr. W., of Whitehaven, at about thirty years of age weighed twenty-three stone, ate and drank with great freedom, and in great abundance. He became at length so lethargic that he frequently fell asleep in the act of eating, even in company. By the advice of Dr. Gregory of Edinburgh, he took a great deal of exercise, lived sparingly, and slept little. The prescribed diet was brown bread and tea; but the patient, finding it necessary to fill his stomach, ate a great quantity of apples: and to enable him to take the necessary exercise, he found a pint of port or sherry per diem indispensable. He retired to rest at eleven, and rose between four and five o'clock. His only medicine was three brisk purges a week. By this system he reduced himself to fifteen stone, with great improvement to his health. (Wadd, p. 85.)

A baker, living in Pye-corner, attained the weight of thirty-four stone, and could not move out of his chair for many years. He would frequently eat a small shoulder of mutton five pounds weight, and proportionably of other things, and drink a gallon of good beer. He was moreover of a costive habit, and required four times the strength of an ordinary purgative to operate on him. He with great resolution persisted for one year in living on water-gruel and brown bread, and lost nearly two hundred pounds of his bulk. (Wadd, p. 102.)

These cases sufficiently prove the efficacy of a plan of abstinence; but there are cases in which its application will require some caution and modification. It is especially in relation to the treatment that we wish to preserve the distinction between the sthenic and asthenic varieties of obesity. The former will bear measures that would be insufficient or unsafe in the latter. Thus a sudden and total prohibition of animal food and fermented liquors would lower the circulation, already too languid in the asthenic form; and by retarding the absorptive process, and weakening the locomotive powers too much for exercise, change the disease from obesity to a cachectic dropsy. Experience has shown, on the other hand, that persons of robust constitution, when affected with obesity, may with impunity even abruptly reduce the quantity and quality of their aliment, and with the most beneficial results. The inexpediency of laying down any absolute plan for the treatment of obesity will, therefore, be obvious; and the necessary distinctions may very well be comprehended in the two kinds into which we divide them.

Treatment of sthenic obesity.—The circulation is here supposed to be vigorous, the digestion good, and the absolute strength not impaired; although the activity be greatly diminished by the inroads of the disease. The indications here are, therefore, 1. to remove the accumulated fat; 2. to exclude from the system all material of nourishment beyond what is necessary to supply the demands of the excretions; 3. to ensure that the nourishment that is taken in be applied only in this way. All these indications may be fulfilled by diet and exercise.

The food should be very moderate in quantity; this is the most important point, and the next is that it be not too nutritious in quality. The breakfast may consist of tea and brown bread (not more than four or five ounces) without butter. If there should be a feeling of great exhaustion in consequence of the scantiness of this allowance, a dried herring or a hard-boiled egg may be added. The brown bread which is made by several bakers in London, containing the finer particles of bran and a proportion of rye-flour, is to be preferred, as it is less nutritious, and acts on the bowels more than any kind of bread or biscuit. As long as active exercise can be persisted in, we do not think it advisable to exclude entirely the use of animal food. A few (three or four) ounces of lean meat, white fish, poultry, or game, with a proportionably sparing quantity of the less nourishing vegetables, such as greens, turnips, pulse, sorrel, chiccory, &c. with two or three glasses of white wine if required, may constitute the dinner. If the absence of the habitual quantity produce a painful sensation in the stomach, the only supplement that may be added is a cucumber or salad without oil or egg in the dressing; or, if preferred, an orange or two, an apple, or a few gooseberries, strawberries, or currants, with little or no sugar

may be taken to allay the cravings of a dissatisfied appetite. Although it is desirable not to tempt by variety, nor to allow more than three articles for the principal meal, yet the varying of these from day to day keeps the stomach in tone, and reconciles the patient somewhat to the difficult task of great moderation. Very little liquid should be taken during dinner, and the liquid meal after it should be restricted to a single cup of tea or coffee with little or no sugar or milk; for we are convinced that copious libations of any kind at this time hurry the chyle into the circulation in an imperfectly assimilated state, and, therefore, more abounding in oily particles. There should be no solid food taken after dinner; or if the appetite be very craving, an orange, a roasted apple, or a cup of thin gruel with a little lemon-juice in it, taken half-an-hour before bed-time, should suffice; these contain but little nourishment, and tend to keep the bowels in a soluble state.

The habit of active exercise is quite as necessary as abstinence, and it requires as much resolution to observe it. In advanced stages of obesity, horse-exercise is almost the only kind that can be pursued, the legs being unequal to support their burthen for a length of time sufficient to be useful; but the patient must submit to the roughest paces of his sturdiest horse. When walking can be accomplished, the legs must not be spared: this is the best exercise to reduce bulk, both because it can be more readily resorted to and longer persevered in, and because, being most general, it excites the excretions more than other kinds. It may, however, with advantage be varied with digging, rowing, dumb-bell exercise, and various other gymnastic pursuits. At least two hours out of the twenty-four should be imperatively devoted to the energetic practice of some of these modes of exercise; and the more beyond this, the speedier will be the reduction of bulk. Corpulent persons ought to limit their period of sleep as much as possible, by rising early to take a walk or some exercise before breakfast, and the disposition which they frequently have to sleep during the day and after meals should never be indulged in.

A very salutary kind of exercise, and one that may conveniently be allotted for the fasting task, is vigorous friction of the limbs and body by the hands or with a flesh-brush; and this may be advantageously preceded by the shower-bath, or copious cold ablution. These means promote the action of the absorbents, and improve the tone of the cutaneous circulation.

There is little need of medicines in the slighter degrees of sthenic obesity; for the functions are generally pretty well performed. If the bowels require aid, and the dietetic means before recommended fail, a black draught or a colocynth pill occasionally will suffice. But in more advanced states purgatives may be indicated as depletories, especially if there be also determination to or congestion of blood in the head; in this case calomel and jalap, alternated with salts and senna, or the compound gamboge pill, will be required twice or three times a week. It has been thought useful in some cases to diminish the appetite for food by squill, ipecacuanha, and other nauseating medicines we do not recommend this generally, as nausea is a weakening influence, and renders exercise a painful effort; but there may be cases in which the natural appetite cannot be stinted without real suffering: in these, small doses of ipecacuanha, or, what is better, dissolving in the mouth a camphor lozenge or smoking a cigar, may occasionally be resorted to, to relieve this craving sensation. As to vinegar and other acids, which formerly were reputed remedies in obesity, we cannot but follow Cullen in condemning their use, since their effect is only in proportion as they counteract the digestive process, and the risk which they entail, of exciting chronic diseases of the stomach and bowels, far outweighs their thinning powers, which often fail when unsupported by diet and exercise. Soap and alkalies were highly recommended by Dr. Flemyng, (Discourse on Corpulency, London, 1780;) and as they have a certain chemical affinity for fat, and increase the secretion of urine, they seem to promise advantage: but the illustration of their efficacy in the case described by Dr. Flemyng falls greatly before the numerous examples of cure by abstinence and exercise. As adjuncts to these means, alkalies may prove beneficial, and especially in the common complication of gout with obesity, ten to twenty grains of soap in the form of pills, *m.*xv to xxx of the liquor potassæ, or four to eight grains of the subcarbonated alkalies in ℥i of camphor mixture, may be given twice or thrice in the day.

Treatment of asthenic obesity.—The indications here are to increase the activity of the functions of circulation and absorption, and to improve the tone of the digestive and locomotive organs.

Abstinence is an important agent in this as well as in the other kind of obesity, and the outline of the diet before sketched may be followed here; but the reduction of the quantity of the food must be made more gradually, and the quality with greater care adapted to the powers of the digestive organs. Thus, if there be a disposition to gastric irritation, the milder and more farinaceous articles are to be chosen, their quantity being still limited; but if a nervous dyspepsia accompany the obesity, which is the commoner case, such kinds of animal food which have been already recommended, together with a little spiced rice and a small quantity of white wine, once a day, are more eligible; no salads or supplements of any kind being allowed, and the breakfast being restricted to biscuit or dry toast, with tea or coffee. The quantity of these articles must be gradually but steadily diminished as far as the strength and general health of the patient will permit.

The defect in muscular power which commonly attends asthenic obesity considerably limits the means of exercise. Horse exercise is still generally practicable; and the oftener it is resorted to, the better. An important substitute may be obtained in friction of the body and limbs; this is a powerful mean of promoting the absorption of superfluous matter, and of giving vigour to the sanguineous circulation of the surface. Where there is a relaxed state of the body and an easily perspirable skin, friction should be preceded by the salt-water plunge or shower-bath; but where the skin is harsh, with a deficient reactive power

of the superficial vessels, it may with the greatest advantage be combined with the vapour-bath in the manner of Indian shampooing, which is very effective in giving laxity and freedom to the cutaneous circulation. In proportion as the muscular strength is restored, it must be engaged in other kinds of exercise to the utmost of its power; and in the ratio of its increase will be almost infallibly the diminution of the torpid bulk of the body and its accompanying disorder.

As there is often considerable derangement of the organic functions, the aid of medicines is frequently required in asthenic obesity. Those most needed are those which increase the excretions, and improve the tone of the animal fibre; and by a judicious administration of such evacuants and tonics much good may be effected. If there be a deficiency in their action, the bowels must be moved; but strong cathartics are not eligible, as they disorder the digestive function, already weak, and weaken the whole frame. In common constipation, or torpidity of the whole canal, aloes in the dose of three to five grains, with a grain of sulphate of iron, twice a day, is exceedingly well adapted to fat phlegmatic subjects with languid circulation. If the colour of the evacuations indicate a defective secretion of bile, a very common symptom in this form of obesity, calomel or blue pill must be occasionally combined with these medicines; and if there be such a torpidity of the absorbent function as to cause œdema, pitting, on pressure, in the fat of the legs and feet, two or three grains of gamboge may properly be added. Great advantage may in some cases of the same kind be derived from a course of a saline chalybeate water, as that of Cheltenham.

Of tonics, the alkaline preparations of iron are the most eligible, as they seem to facilitate the conversion of chyle into blood, and promote the secretion of urine, without increasing the appetite for food. The mistura ferri composita, and the tinctura ferri ammoniata are the most convenient preparations; and an attenuant and diuretic effect may also sometimes be usefully obtained by joining with them a little carbonated alkali and nitre. In no cases is this treatment more beneficial than in the obesity which occasionally accompanies defective menstruation in females; and whether this disorder be a cause or only a concomitant, it is highly important that the periodic evacuation be restored to its normal proportion.

Analogy suggests that considerable benefit might be obtained from the use of iodine, in its known sorbefacient capacity, in the asthenic forms of obesity; but we are not authorized by direct experience to recommend it. Where other complaints, such as dyspepsia, dropsy, &c., are complicated with obesity, they must be treated in the usual way. Obesity may, however, furnish a reason for modifying our practice when the subjects of it are attacked with other diseases. Fat persons do not generally bear bleeding well; purging suits them better: but they are often more readily lowered by any evacuation than their appearance would lead us to expect.

The period during which it is necessary to pursue the treatment recommended above can only be determined by the effect produced. It may be useful and satisfactory to the patient to put to the test of the balance the beneficial operation of his plan; but a restored activity, and the removal of the discomforts of obesity, give a surer criterion of his improvement; if these are accomplished, although he should still retain some largeness of bulk, there is no longer reason to consider it a disease. The return to a more generous method of living, should, however, be made very gradually, and with circumspection; and nothing should deter the individual from pursuing those habits of active exercise that have mainly contributed to free him from his burthen.

C. J. B. Williams.

[OBSERVING, METHOD OF. See Statistics, Medical.]

ŒDEMA, (οἴδημα, from οἰδέω, *to swell.*)—This term properly signifies a swelling of any kind, but is now confined to a swelling of a dropsical nature, situated in the cellular tissue. When the œdema is developed under the skin, it appears in the form of a tumour, which retains the impression of a finger, or any other body that has been applied with a slight degree of force to the surface. It has usually been regarded as a species of anasarca; and unquestionably it has much analogy with this affection. In the present article, however, we shall confine ourselves to the consideration of those œdematous affections which are not connected with a general dropsical diathesis, and which may exist for an indefinite length of time without extending beyond the original site.

Œdema appears under very different circumstances; and we are inclined to believe that, at different times, the nature of the effusion into the cellular membrane is different; the external appearance certainly is so. We are not, however, able to prove that such a difference does exist; and we shall therefore content ourselves with stating the different circumstances under which a swelling, having the character we have assigned to œdema, may happen, and the variation of treatment which such differences demand.

Œdema exists in the commencement of phlegmonous inflammation through the whole extent of the affected part; and throughout the progress of inflammation, it occupies the extreme boundaries of the diseased part in a greater or less degree. In some instances, in consequence of the nature of the affected parts, the inflammation does not pass beyond the œdematous stage before it proves fatal. Such appears to be the case in the disease to which the term *œdema glottidis* has been assigned, the cellular membrane of the glottis being the seat of a serous infiltration, which gradually closes the rima glottidis, and destroys the patient by suffocation. [See Laryngitis.] In pneumonia, also, portions of the lungs are found in the œdematous stage, the similarity of which to anasarcous effusion has been remarked by Laennec. More commonly, however, the inflammation proceeds to induration and suppuration, at least of the centre, and the œdema is found only in the circumference. M. Gendrin has given an account of the pathological state of the cellular tissue in this, which he terms an active œdema. He has derived his information from observing the processes set up in the cellular tissue in the neighbourhood of a wound.

The cellular membrane close to the wound is hard to the touch; its areolæ are infiltrated with a reddish, opaque, and gelatinous matter, and pressure gives issue to a reddish, opaque, and mucus-like serum. Beyond the inflammatory redness, there exists during life a serous infiltration which is rather elastic; and this infiltration is greater in proportion to the natural relaxation of the cellular tissue, and the inferior situation of the part. After death the œdema increases, but the elasticity diminishes. The œdema extends into the intermuscular cellular tissue, and the vessels of the part are evidently enlarged.

Of the treatment of this kind of œdema we need say no more than that it is that which is appropriate to inflammation, of which indeed it is only a stage. (See INFLAMMATION.)

The affection which has been termed "skin-bound," and which occurs in infants, is also a variety of œdema; but as Dr. Carswell has given an excellent account of it under the head INDURATION, we shall refer the reader to that article for information respecting it.

Œdema is a common consequence of rheumatism, particularly of that form which is called *arthritis rheumatica*. It may either be the remains of the active inflammation of the joints, or it may from the first appear as simple œdema. It may occur in the knees and ankles, but the most common situation is the back of the hands. It forms a cold, thick, puffy swelling, and generally white, and it is sometimes, but not always, rather tender. It is frequently the seat of dull aching pain, and the patient can make very little use of the limb. The fingers are stiff, and the hand cannot be closed. When the affection is recent, fomentations frequently repeated, and continued for half an hour at a time, will sometimes remove it very quickly, and the patient is cured as it were by a charm. More commonly fomentations are useless, as also are local warm and vapour baths; they do not even afford a temporary relief. Stimulating mercurial liniments are more useful, and generally succeed in removing the œdema in the course of a month. Dr. Elliotson appears to have employed the hydriodate of potash, but we have ourselves had no experience of it in these cases. When, however, the mercurial liniment fails, as sometimes it will, the preparation in question may make a good substitute. Its property of increasing absorption certainly points it out as a probable remedy. Occasionally a certain degree of œdema will remain during life, the patient having at the same time a tolerably free use of the limb.

While the treatment is thus directed to the local affection, the state of the general health must not be neglected. Few diseases, perhaps, are more manifestly attended with disorder of the digestive functions than rheumatism, and this disorder is not unfrequently aggravated by the remedies which are employed in the acute stage. Unless, however, when this stage is past, immediate attention be paid to the state of the digestive organs, the disease, even in its acute form, is very liable to return. The treatment of rheumatism becomes, therefore, the treatment of dyspepsia, and only by success in relieving this latter affection can we hope permanently to relieve the former. (See RHEUMATISM.)

Œdema is one of the most common attendants upon amenorrhœa. Amenorrhœa itself depends upon two opposite states of the system, a state of plethora, and a state of debility and exhaustion. In both of these œdema may exist. In the former, or the plethoric state, together with the common symptoms of plethora, there is usually much pain in the lower extremities, particularly in the lower part of the leg and round the ankles; and this pain is worse towards night, at which time also the œdema is much more considerable than in the morning. Upon examining the legs, the parts corresponding to the pain are usually cold to the touch, hard, and of a purplish colour; and this colour varies from a very light tint to an actual livid hue. It sometimes resembles purpura so far as the colour is concerned, but there is evidently no extravasation. At other times real purpura exists, and many petechial spots are present. The œdema is usually in these cases very firm, not readily yielding to the finger, and the impression is very quickly effaced. Frequently there is considerable tenderness in the course of the femoral vein, and the most common site of this tenderness is just before the vein pierces the tendon of the triceps to pass into the ham. This variety occurs in girls of a florid appearance and plethoric habit, and the usual period of its occurrence is between eighteen and twenty-five years of age. The tenderness of the vein, which probably depends upon some inflammation of the vessel, is not, however, peculiar to this diathesis, nor to this period of life. It frequently occurs in that condition which is neither very evidently plethoric nor feeble, and which equally resists an extreme mode of treatment, whether depleting or tonic. The countenance of these individuals is sallow and unhealthy, but does not exhibit that fair and pellucid appearance which distinguishes those who are the subjects of œdema in consequence of exhaustion.

The individuals last mentioned exhibit the common symptoms of amenorrhœa from debility, the quick, rolling, and easily compressible pulse, the palpitation of the heart, excessive nervousness, &c.; and the œdema of the lower extremities is both more considerable than in the former varieties, and much softer. It yields readily to the fingers, and retains their impression for some time. In some persons the œdema is so great that the swollen part overhangs the shoe excessively towards evening; and though it disappears during the night, when the patient is in bed, it returns in two or three hours after rising, gradually increasing till evening, when, from the weight and stiffness of the limbs, the patient is compelled to place them in the horizontal position, the only position in which she can obtain ease.

Œdema occurs also in women at that period which is known as *the change of life*, and is in this case, so far as our experience extends, always dependent upon a plethoric state of the system. It varies from the œdema which we have described as occurring in young persons of a florid complexion, by the absence of the livid colour, and by the swellings being much less firm and resisting.

The description above given of the different circumstances under which œdema occurs, sufficiently points out the proper mode of treatment.

In the first, or plethoric variety, not only must the general remedies be employed, as bleeding and purging, but if there be any tenderness in the course of the femoral vein, leeches should be applied to the tender part, and they should be repeated again and again, so long as any tenderness remains.

The second or middle variety requires a mixed treatment, as we have already indicated; leeches, if any tenderness is present in the course of the femoral vein, and alternate tonic and depleting remedies as the symptoms vary.

The œdema in the third variety, in which the system is suffering from exhaustion, is most benefited by the exhibition of steel; but for a more complete direction for treating these cases we refer to the article Amenorrhœa, of which disease œdema is usually one symptom.

When œdema occurs at the change of life, there are so many symptoms which intimate a plethoric state, that there can be no hesitation in recurring to depletory measures, both bleeding and purging; and as the œdema is very liable to return, till the catamenia are entirely suspended, the repetition of these remedies will be required as often as this happens.

Old persons are frequently subject to œdema of the lower extremities, and which, as their debility increases, extends higher and higher towards the trunk, yet seldom assumes the general phenomena of dropsy, there being neither a decrease in the flow of urine, nor any other inconvenience experienced excepting what is the consequence of the weight and stiffness of the limbs. Sometimes it seems to become at length connected with a dropsical diathesis, and after many years have elapsed, during which this œdema has remained stationary, ascites and general anasarca ensue.

So long as the disease remains merely in the state of œdema, nothing more is required than to support the integuments by means of a laced stocking or bandages; when, however, dropsy supervenes, it must be treated upon the principles which have been laid down in the article Dropsy.

Excessive fatigue is also a cause of œdema. Soldiers, after long marches, are subject to swellings of the ankles, and the œdematous state of the legs of horses after over-work is well known to horse-keepers, who are also aware that it is merely a state of debility; hence they bandage the legs of such horses in the stables, that the cellular tissue may have an opportunity of recovering its tone.

Œdema will also be caused by any thing which obstructs the circulation of the blood through the venous system; hence it is common in the latter months of pregnancy, from the pressure of the uterus upon the iliac veins. Ligatures also have a similar effect. The presence of œdema in the arm in cancer of the breast is probably to be accounted for on the same principle. It seldom happens till the disease has made considerable progress, and in the cases which have fallen under our notice, the axillary glands have been much affected. In our experience this œdema is much more common after the removal of the breast, and upon the recurrence of the disease, than in those cases in which no operation has been performed.

These appear to be the principal forms under which œdema may appear. How far this is an affection really different from anasarca may certainly be questioned; there is, however, in all the cases we have referred to, this peculiarity, that the affection is entirely local; that it by no means necessarily leads to dropsy; and that life may terminate without any apparent progress being made in converting it from a local to a general affection of the system.

John Darwall.

OPHTHALMIA. Under this head it is proposed to consider inflammation of the conjunctiva only, although, strictly speaking, the term is more applicable to inflammation of the eye itself.* The universal use of the term to designate inflammation of this membrane has probably arisen from this being the most frequent and obvious inflammatory affection of the organ. In approaching the consideration of this subject the student should first pause to ascertain whether his knowledge of the structure and functions of the conjunctiva enables him to announce the changes reasonably to be expected from inflammation of its texture, and afterwards should determine whether observation justifies his anticipations. The conjunctiva being a modification of the common tegumentary membrane, intermediate between the skin and mucous membrane, the changes produced by inflammation are of the same character as those induced by the same cause in these two structures. These changes are, increased vascularity, tumefaction, pain and altered secretion. The increased vascularity is characteristic: when the inflammation is slight, the enlarged vessels present the appearance of a distinct red net-work spread over the white sclerotic when more intense, the appearance of distinct vessels is lost, and the surface assumes a uniform deep red colour. The tumefaction is inconsiderable unless the inflammation be very severe, in which case the vessels become enormously distended with blood, and the subjacent and surrounding cellular membrane loaded with serum, constituting the appearance technically denominated *chemosis* on the globe of the eye, or producing a most distressing prominence of the lids. The pain is uniformly at first such as is produced by the presence of a grain of sand beneath the eyelid, but it subsequently is accompanied by a sensation of heat, producing the same description of distress as arises from a scald. The intense aching pain experienced in violent inflammation arises from the globe of the eye becoming involved in the disease. The conjunctiva being lubricated by a fluid derived from a source different from its own surface—the lachrymal gland—the first alteration in the nature or quantity of the secretion from the surface cannot be ascertained. The alteration, however, becomes speedily obvious, and is as characteristic of the disease as the other changes enumerated, purulent matter in considerable quantity being poured out. It must not, however, be assumed that the secretion of purulent matter is a necessary consequence of conjunctival inflammation; instances of the contrary will presently be adduced.

Inflammation of the conjunctiva presents the distinct characters above enumerated, because it is

*[At the termination of this article, inflammation of other parts of the eye has been added.]

inflammation of a structure of equally distinct anatomical character, but it is so completely modified by circumstances, that few other inflammatory diseases appear in so many different specific forms. The inflamination of this membrane is either circumscribed in the form of pustule, or diffused, as in the different varieties of purulent ophthalmia. Either or both of these are again modified by the presence of other diseases, and hence gonorrhœal, variolous, and other distinct species.

Inflammations of the conjunctiva may, therefore, be divided into *pustular* and *diffused;* the *pustular* into common pustular and variolous, and the *diffused* into catarrhal, severe purulent, gonorrhœal, and the purulent of infants. The grounds upon which these specific distinctions are established will be stated as each is submitted to inquiry.

While considering the nature of conjunctival inflammation in general, it is expedient to consider also the principles which are to guide us in the treatment of that inflammation. The resources available for the removal of inflammation in other structures are equally available in this. The activity of the circulation is to be diminished by general and local bloodletting—the contents of the stomach and bowels removed by emetics and purgatives—the condition of the system which nauseating medicines produce is to be induced — inflammation in the vicinity, or counter-irritation as it is called, is to be excited by blistering—the temperature of the inflamed part is to be lowered by cold applications — or the condition, whatever it may be, which warm moisture causes, should be encouraged by warm fomentations. In conjunctival, more than in any other form of inflammation, the practitioner has had recourse to the immediate application to the part of those remedies to which astringent, sedative, or irritating properties are attributed, and in considering their application to each form of disease, their comparative value will be submitted to inquiry. Particular circumstances may demand additional remedies or peculiar management — the inconvenience arising from accumulation of purulent discharge is to be avoided—the gumming together of the lips obviated—the vessels of the surface may require to be opened by scarification, or the serum of *chemosis* discharged by puncture. It may be necessary to produce the peculiar constitutional effects of mercury—to encourage the secretions of the skin, intestines, or liver—to restore the flow of milk from the breasts — to regulate the functions of the uterus—or to reproduce suppressed discharge of blood from piles. The consideration of conjunctival inflamination in detail will prove the importance of paying the most careful attention to the differences of constitution presented by different individuals, in order to substitute tonic medicines, and invigorating diet and regimen, for a system of depletion and abstinence. It is obvious that each specific form of this disease will require a corresponding variation in the application of these principles, and that the treatment must be modified with every modification of the symptoms induced by circumstances.

In studying the progress and treatment of conjunctival inflammation, the practitioner should never lose sight of the marked and important distinction to be drawn between the inflammation and its consequences. Hitherto this distinction has been so far made as to form a division of the disease into the acute and chronic stages, but it is worth considering whether the condition which is called the chronic stage should be considered analogous to that which exists during the inflammatory or acute stage. The alteration in the treatment to be adopted when the disease assumes the chronic form, and which is carefully inculcated by every practical writer, proves that those symptoms which are to be subdued by depletion and other similar means have disappeared. It is true that the increased vascularity, augmented and altered secretion, and even painful sensation still exist, but in a very different degree, and of very different character. The tense, tumid, glazed chemosis subsides, and is succeeded by a soft, pulpy, villous vascularity ; the secretion from the surface is profuse, and its purulent nature more remarkable, and the painful sensation is mitigated and unaccompanied by the scalding which characterizes the distress of the inflammatory period. The eye is not injured or destroyed by conjunctival inflammation unless the inflammation extend to the other textures, producing sloughing of the cornea, or suppuration of the eyeball; or unless it produce the altered or disorganized state of the membrane which leads to vascularity or opacity of the conjunctiva covering the cornea, or granular condition of the lining of the lids.

1. Mild Inflammation of the Conjunctiva. — That there is a form of conjunctival inflammation entitled to the above appellation, which presents a specific character perfectly distinct from every other, there can be no doubt. It is rather vaguely defined by authors under the title of catarrhal ophthalmia, but does not appear to be considered so completely different from the severer purulent ophthalmia as its history, at least according to the writer's experience of the disease, in Ireland, warrants. It is distinguished, as the title implies, by the comparative mildness of its symptoms, the vascularity never passing into true chemosis, or inducing sloughing of the cornea; the pain not being so severe, and the purulent discharge being much less copious. It occurs in spring and autumn, is epidemic or endemic, and, whether contagious or not, attacks several individuals in the same family. It affects young persons more frequently than adults, and sometimes seizes a great number of children in schools or other institutions where they are collected. The following is the history of the disease: The patient experiences a sensation of itching, with slight uneasiness, as if a mote or eye-lash had passed beneath the lid, which is greatly aggravated by the efforts made to remove it by rubbing or handling the eye. If the organ be now examined, nothing more can be discovered than an increase of vascularity, with a copious flow of tears. Next day all the characteristic symptoms may be recognised. The conjunctiva lining the lids, especially the lower, has acquired a uniform deep red appearance, and that covering the sclerotic, presents an equal vascular network, permitting the white structure of the former membrane to appear in the meshes or areolæ; the vessels not crowding together so as to produce the deep general redness

of the chemosis of severe ophthalmia. This vascularity is well represented in Mr. Wardrop's work on the Morbid Anatomy of the Eye, which contains more well-drawn and faithful representations of diseases of this organ than any other accessible to the student. There can be no difficulty in distinguishing this characteristic vascularity from the equally characteristic vascularity of the sclerotic in internal inflammation of the eye. The high degree of vascularity, with prominence of the membrane from effusion of serum beneath it, constituting the appearance denominated chemosis, never perhaps exists in mild purulent conjunctival inflammation, and therefore, when it does occur, must be considered evidence of the presence of the severer form of the disease. The secretion of purulent matter from the surface is most obvious after the night's rest; the eye-lashes are gummed together by it; clots produced by the evaporation of the more fluid parts of the discharge are formed at the angles; and when the lower lid is depressed, flakes and films of it may be observed in considerable quantity. The existence of purulent discharge is not so obvious in the course of the day, especially if the patient has been in the open air, the irritation of the surface causing such a flow of tears as removes it as fast as it is secreted. In this case, inquiry should be made as to the state of the eye upon awaking in the morning, and the patient should be allowed to remain for a quarter of an hour with the eyes closed, when, upon depressing the lower lid, flakes of yellow matter may be seen floating in the tears. The sufferer experiences repeated attacks of scalding pain, with copious flow of tears, so much resembling the effects of a mote or grain of sand beneath the lid, that he can scarcely be persuaded that such does not actually exist. Vision is not very materially impaired during the prevalence of these symptoms, but there is generally a slight degree of haziness experienced, especially when looking at the flame of a candle, and occasionally alarm is excited by tenacious films of purulent matter adhering to the cornea.

The symptoms here enumerated continue for two or three days; the period depending much upon the circumstances under which the patient is placed: they then begin to yield and alter, the painful sensation of a foreign body beneath the lids, with scalding and flow of tears, becomes less frequent, the vascularity loses its intensity and shining appearance, and the purulent discharge is more freely secreted. Subsequently, these symptoms gradually diminish and finally disappear, leaving the parts somewhat more vascular and irritable than before this attack; but in a few weeks this condition disappears, and the recovery is complete. That this is the true history of the symptoms, progress, and termination of mild conjunctival inflammation in a healthy subject can scarcely be denied; but it is not the history of the disease as it is observed in daily practice. This simple form of inflammation must obviously disappear after passing through its different stages, unless the natural processes tending to recovery be interrupted. This interruption, however, generally takes place. The disease is frequently exasperated, and the efforts of nature to restore the healthy functions of the part suspended by injudicious, unnecessary, or injurious interference; or it is so modified by scrofulous constitution, or by neglect, filth, and deficient food and clothing, that its character is totally altered.

The treatment of mild conjunctival inflammation is as obvious as the disease is simple. The bowels should be emptied, and the secretion from the mucous membrane of the intestinal canal excited by purgatives in moderate and repeated doses. The infusion of senna and tamarinds, with the addition of sulphate of magnesia and of tartrate of antimony in the proportion of a grain to eight ounces, may perhaps be preferred for this purpose. The abstraction of blood by the lancet is seldom required; but it is frequently necessary to apply eight or ten leeches to the hollow of the temple behind the external angular process of the frontal bone, or over the cheek-bone. The bites of leeches in the thin and flaccid skin of the eyelids generally produce so much irritation and inflammation, that their application there is often injurious. Locally, cold or warm applications may be resorted to, according to the relief the patient experiences from one or the other. If there be much heat and scalding pain, a light fold of old linen, wrung out of cold water, may be laid over the closed lids, and changed as it becomes warm; or a soft sponge or scrap of flannel, wrung out of hot water, and held in the hollow of the hands beneath the eyes, may be used to induce the soothing effects of warm moisture. At bedtime the edges of the lids should be smeared with cream, unsalted butter, or any other oily application not rancid or burned. Rest of the lids should be enjoined, as the constant friction of the surface greatly increases the irritation; the eyes should be kept closed as much as possible; but the patient should not be immured in a dark room, or have his eyes covered with a shade, as is frequently practised. The propriety of applying astringent washes to the inflamed surface during the first stage of the disease may be justly questioned. It is not to be denied that such applications may have the effect of arresting the progress of the disease at once; but if they have not that effect, they are liable to produce an increase or irritation. In Dublin, where no adequate relief is afforded to the destitute poor in their own homes, it is often expedient to endeavour to cut short the disease by the direct application of a strong astringent solution, to prevent the establishment of that chronic vascularity and opacity of the cornea which filth, starvation, and rags would otherwise produce. For this purpose, a saturated solution of acetate of lead or alum may be resorted to with perfect safety and decided effects, and a few drops introduced between the lids every night and morning. To remove the vascularity and that condition which accompanies the secretion of purulent matter, weaker astringent solutions may be used more freely. Five grains of alum or of the acetate of lead to an ounce of water, make a wash as efficient and safe as any other of the various salts resorted to for this purpose: the comparative value of these will, however, be presently considered.

In addition to the above observations, an abstract of Mr. Lawrence's valuable account of catarrhal ophthalmia, delivered in his lectures,

may not be inappropriate. He observes that it originates from atmospheric causes or peculiarities, is caused by exposure to cold, and corresponds to catarrhal affections of other mucous membranes. In individuals predisposed to this affection, being out in an east wind for a quarter-of-an-hour, or half-an-hour, will sometimes infallibly bring on an attack. He enumerates the following symptoms: — stiffness, smarting, uneasiness from exposure to light, watering and external redness, followed by mucous discharge, without considerable pain or intolerance of light. The conjunctiva becomes of a scarlet colour in mottled patches at first, but subsequently of uniform appearance, the redness commencing at the circumference, and extending to the cornea. Sometimes spots of ecchymosis occur in the vascular network from the activity of the inflammation, and occasionally pustules round the margin of the cornea; but true chemosis never exists. The characteristic symptom of a sensation of a foreign body beneath the lid he attributes to the irregularity of surface produced by vascular distension. The secretion from the surface is at first thin, but subsequently becomes of a thicker consistence and whiter colour, resembling pus, at first confined to the inner angle of the eye, or to the fold of reflection of the conjunctiva, but afterward is poured out in sufficient quantity to agglutinate the lids at night. These symptoms are accompanied by those of inflammation of other mucous membranes, and are found to remit by day and to become exasperated at night. The affection, he says, passes through a certain course and then subsides, yields readily to treatment, and is, generally speaking, free from danger unless improperly treated. It is distinguished from the severe purulent ophthalmia by its milder character; and although the appearances of the two approximate, yet the difference is rather in degree than in kind. The disease, he observes, demands mild antiphlogistic treatment: cupping and leeching in ordinary cases, and occasional venesection in full habits; an active aperient, sometimes an emetic, followed by saline and sudorific medicines and diluent drinks. Locally, he recommends warm in preference to cold applications; but observes that the latter are sometimes comfortable to the patient, and not injurious; and after the inflammation subsides, suggests the application of blisters, exposure of the organ to the air, and he objects to shading the eye unless there be intolerance of light.

2. Severe Inflammation of the Conjunctiva, commonly called Purulent Ophthalmia.—The severer form of conjunctival inflammation presents itself in three different shapes, the *Egyptian*, or, as it is called for distinction, the *purulent* ophthalmia, *gonorrhœal* ophthalmia, and *purulent* ophthalmia of infants. These three forms, if not specifically distinct, and characterized by peculiar symptoms, are at least distinguished from each other by origin, history, progress, and consequences. The common severe purulent ophthalmia is to be now considered. This disease probably always existed in the form in which we at present occasionally observe it; but the attention of the profession was particularly called to it upon the return of the troops from Egypt, among whom it spread with such uncontrollable violence and destructive consequences, that it acquired the title of Egyptian ophthalmia. The following history of the disease, as it occurred at that period, is extracted from Dr. Vetch's Treatise on Diseases of the Eye. "The British army which formed the first expedition to Egypt left that country in three divisions. Great part of the whole touched at Malta, and a considerable portion also at Gibraltar, at which places ophthalmia not only continued to present itself in the regiments which had brought it with them, but was communicated at the former place to several women with whom the soldiers associated; and at Gibraltar it became from that time by no means an unfrequent complaint among the troops who had never been in Egypt. On the whole, however, the climate of Gibraltar has proved rather favourable than otherwise to the amelioration of the complaint. From Malta and Gibraltar the greatest part of the army proceeded to Great Britain and Ireland. In two regiments of fencibles disembarked at Portsmouth, the disease continued to present itself from the time of their landing until they were disembodied a short time afterwards. The regiments disembarked in Ireland having been placed in the same barracks and garrisons with the Irish militia regiments, the infection appears, from such evidence as I have been able to obtain, to have been communicated to them. If the disease existed at all in England, it seems to have been entirely overlooked till the summer of 1804, when it appeared with alarming violence in the second battalion of the fifty-second regiment, at that time stationed with the light infantry division in barracks, near Hythe in Kent. Not a man of this battalion had been in Egypt, and it was entirely composed of a body of volunteers received in one draft from the Irish militia, and very shortly after their arrival at Hythe the disease made its appearance. It continued to disseminate itself more extensively in this regiment during the remaining part of 1805; and in the following summer of 1806 it also began to prevail in the first and second battalions of the forty-third regiment, and the first, second, and third battalions of the 95th, all stationed at the same place and under the same command. Whether the disease was spread from the battalion in which it first commenced, or was derived from the same source, that is, the Irish militia, of which the others were equally composed, it would be now difficult to determine. The battalion in which this renewal of the infection first showed itself in this country was the second of the fifty-second, and a very considerable number of cases had occurred in the first battalion when it embarked for Sicily in 1806. From the time of their landing in Sicily the disease continued to cripple this otherwise fine battalion. Part of the army of Sicily was dispatched to Egypt, and on its return to Sicily a fresh stock of the infection of ophthalmia was brought with it; but the disease, or an infectious ophthalmia of the same character, was in the first instance carried to Sicily from this country by the first battalion of the fifty-second regiment. From this station alone, I believe more than one hundred and thirty cases were sent home totally blind. When the disease had existed for some time in the light infantry brigade, composed, as I have

already stated, of the fifty-second, forty-third, and ninety-fifth regiments, stationed in Kent, it broke out in other regiments which had no communication with the former, but had formerly suffered much from the disease in Egypt, though till this period it had remained either altogether dormant, or prevailed in an extent so limited as to escape attention. Three hospital stations were established for the exclusive reception of those affected with the disease, towards the latter end of 1807, to the superintendence of which I was appointed. The numbers were chiefly composed of men from the regiments already mentioned; but in the summer of 1806 it contained no less than nine hundred cases, consisting of detachments from more than forty different corps. Previously to the sailing of the expedition to Walcheren in 1809, the number of acute and highly purulent cases was also very great, but as they were received in an early stage of the disease, there was little or no eventual loss, and from that period the disease continued to decline."

Dr. Vetch proceeds to account for the disappearance, temporary suspension, and recurrence of the disease, by attributing such recurrence to relapses with return of purulent discharge occurring in crowded barracks. He ascribes the comparative exemption from the disease enjoyed by the French army, to the circumstance of their not being confined to barracks or subjected to fastidious discipline, but bivouacking in the field, or being quartered on the inhabitants of the towns they occupied; and in proof of it, instances the exemption enjoyed also by the English troops in the peninsular war. In Ireland, at the period alluded to by Dr. Vetch, the disease raged with perhaps still greater violence, and in consequence of want of sufficient accommodation for the numerous cases in the military hospitals, wards were opened for their reception in Stevens's hospital under the direction of Mr. Colles, where the writer had an opportunity of observing its extensive ravages, and the comparative value of the different means adopted for its removal. That the disease here spoken of is the same as that now observed, and commonly denominated purulent ophthalmia, can scarcely be doubted; and although its appearance among the troops in Egypt, and its subsequent history, has conferred upon it a certain distinction of character, yet it can scarcely be denied that it existed previously, and perhaps more particularly in Ireland.

The condition or symptoms which characterize the severer forms of conjunctival inflammation or purulent ophthalmia, whether Egyptian, gonorrhœal, or infantile, are the chemosis or turgid vascularity with effusion of serum into the subjacent cellular membrane; sloughing, abscess, or ulceration of the cornea; and alteration in the structure of the conjunctiva leading to granular lids and vascular and opaque cornea. The symptoms as they actually occurred in the form of the disease just alluded to are so well described by Dr. Vetch, who enjoyed ample opportunities of observing the disease, that his account is here introduced. "The first appearance of inflammation after the application of the virus is observable in the lining of the lower eyelid. It assumes first a mottled appearance and then a fleshy redness. A little mucus is generally present at the doubling of the conjunctiva at its lower part. The disease I know from observation may remain in this state for twelve hours before it invades the conjunctiva covering the eye; sometimes it may be longer; and in some cases where the contact of the virus has been slight, or removed by immediate washing, the disease never went farther than producing the redness of the lining of the palpebra. In sclerotic inflammation the lining of the eyelids preserves in some degree its natural whiteness, especially just under the tarsi, for days and weeks. The progress of the inflammation, when it extends from the conjunctiva of the eyelid to that covering the globe of the eye, is often so rapid as to elude any distinct observation; but frequently it advances more gradually, preserving a defined line, till it extends over the whole membrane as far as the cornea. No part can be said to be more vascular than another, as the whole seems equally injected, and no space unoccupied. The disease is often thus far advanced before the attention of the patient is so much excited as to make him complain; a certain degree of stiffness being sometimes the only sensation which accompanies it. The first and chief uneasiness in this stage of the disease is described as arising from the feeling of sand or dirt rolling in the eye. This sensation is not constant, as it comes on suddenly and as suddenly departs, confirming to the patient the idea of something extraneous being lodged in the eye. I have always observed that its attacks are in the evening, about the time of going to bed, or very early in the morning. Their duration varies; sometimes an attack abates in an hour, and sometimes continues the whole night; those coming on in the evening being always the most severe. This symptom requires particular attention, as its accession is a certain index of the disease being on the increase. From the observations I have already made, its exacerbations and remissions are easily explained. When a vessel on the globe of the eye is first injected and rendered turgid, it excites an uneasy sensation in the conjunctiva of the palpebra, the same as if it moved over a particle of sand or extraneous matter. As the tone of the vessel diminishes, and the lining of the eyelids becomes accustomed to the new feeling, the painful impression ceases. A farther increase of the turgidity of the vessels already distended, or the distension of others, serves to excite afresh this feeling of uneasiness. The time at which I have said that this symptom generally comes on is when the patient is preparing for sleep, because he is then confined to a closer atmosphere; and not only is the eye deprived of the beneficial effects of the open air, but the temperature is farther increased by the closing of the eyelids in the attempts to sleep. The first stage of the disease may be, therefore, characterized by its great and uniform redness, without that pain, tension, or intolerance of light which accompanies most other forms of ocular inflammation; — exactly the reverse of which takes place when inflammation affects the sclerotic coat. From the beginning of the operation of the virus, there is a disposition to puffiness in the cellular texture between the conjunctiva and globe of the eye. The puffiness often suddenly swells out into

a state of complete chemosis; and at other times it makes a more gradual approach to the cornea, advancing equally on all sides; the close attachment of the membrane at this part causes the swelling as it were to double over the margin of the cornea. While effusion is thus taking place upon the eye, œdema is likewise going on beneath the integuments of the palpebræ. This effusion ought to be considered as perfectly continuous with the chemosis arising from the internal surface of the conjunctiva, and following its reflection on the eyelids. To the œdema of the palpebræ, there is no other resistance than what the integuments afford; and, therefore, in a short time, it forms a tumour of astonishing magnitude, and the external swelling may by its pressure prevent the chemosis from acquiring the magnitude which would otherwise occur. This enormous tumefaction of the palpebræ is generally consentaneous with the complete formation of the chemosis, which is when it has reached the cornea and surrounds it. In proportion as the integuments of the palpebræ, by yielding to the œdema, swell out, they drag the tarsus to which they are attached inwards, producing inversion of the eyelid; and the integuments of the upper and lower eyelids meet, forming a deep sulcus between them. To examine the eye, it is therefore necessary, first to introduce the finger to the bottom of the sulcus, and then, by separating the swollen eyelids, to bring out the inverted cilia. Unless our treatment have an immediate effect in reducing the external œdema, few cases admit of any very minute examination of the eye itself. With the accession of the external swelling, the discharge, which was before moderate and consisted of pus floating in the watery discharge, now flows in a continued stream of yellow matter, which, diluted with the lachrymal secretion, greatly exceeds in quantity that derived from the most violent attack of gonorrhœa. The clothes, and anything within the reach of contact, soon become embued with the matter, the smallest particle of which is capable of producing infection. Although the tumefaction may be at first farther advanced in one eye than the other, it generally reaches its maximum of height in both about the same time.

The patient, reduced to a state of great uneasiness by the irritation of the swelling, and by its confining the discharge, begins now to suffer attacks of excruciating pain in the eye itself. This is chiefly what indicates the mischief going on, and from which the patient must be immediately rescued, in order to save the organ. Here it is enough to observe, that the medical adviser must be careful how he allows himself to be lulled into security by any remission or palliation of this symptom. An occasional sensation, as if needles were thrust into the eye, accompanied with fulness and throbbing of the temples, often precedes the deeper-seated pain. This last is often of an intermitting nature, and a period of excruciating torture is succeeded by an interval of perfect ease. Under the latter form, I have met with it in the greatest number of cases, and the exacerbation and remission have often occurred with great regularity. Sometimes the pain shifts instantaneously from one eye to the other, and is seldom or never equally severe in both at the same time; and sometimes, instead of the eye, it occurs in a circumscribed spot of the head, which the patient describes by saying, he can cover the part with his finger. Sooner or later, one of these attacks of pain is terminated by a sensation of rupture of the cornea, with a gush of scalding water, succeeded by immediate relief to the eye in which this event has happened, but generally soon followed by an increased violence of the symptoms in the other. This first sensation of rupture is, when the disease is left to improper treatment, often followed by a second and a third; till, exhausted by its own violence, the attacks become shorter and less severe; not, however, till after the lapse of many weeks, and even months, do they altogether cease. During this stage of the disease, there is seldom the slightest alteration of the pulse unless the lancet has been freely employed. The patient's general health is little impaired, his appetite continues natural, but sleep almost totally forsakes him. As the pain abates, the external tumefaction subsides also, and a gaping appearance of the eyelids succeeds. This may be termed the third stage of the disease. The ciliæ, which before had been pushed inwards, are now separated, and stand outwards. The previous inversion of the cilia may be explained by comparing the palpebra to a sail bent to a rope; the more the sail is distended, the cord is drawn upwards and inwards. The swelling of the second stage having abated, the eyelids are prevented assuming their natural state, in consequence of the granulated state of the conjunctiva which lines them; and now eversion, more or less, takes place. This in general proceeds, however, no farther; but between this state and a complete eversion there is every degree of a diseased or granulated state of the inner surface of the palpebra. In some cases it disappears rapidly and of itself; in others it forms an inveterate disease, and, combined with some degree of sclerotic inflammation, becomes the cause of opaque cornea. The pain of the second stage of the disease arises, in part, from the destructive changes which have commenced in the cornea, aggravated by distension of the eye, consequent upon an augmented quantity of an aqueous humour. The formation of that fluid, I have already hinted, may take place through the medium of the ciliary processes, and the appearance of the cornea gives no reason to suppose that its internal surface partakes of the inflammation, or that the aqueous humour is increased by any morbid effusion. The distension seems entirely owing to an augmented activity in the secreting vessels; and these certainly are situated in the posterior chamber. Neither does there appear any reason to warrant the idea that the ulceration ever proceeds from within outwards. But the distension of the anterior chamber probably favours the escape of the aqueous humour sooner than it would otherwise happen. The swelling and the purulency prevent us from making any very accurate examination to ascertain the progress of the ulcer. The account I have given of it in a former chapter is an analysis of what takes place in ophthalmia. When any large portion of the cornea sloughs, an adventitious and vascular membrane is often produced, which finally forms a staphylo-

ma. In some few cases, I have seen the lens and its capsule exposed without any external covering whatever, and for a short time the patient sees every thing with wonderful accuracy; but as soon as the capsule gives way, the lens and more or less of the vitreous humour escape, the eye shrinks, and the cornea contracts into a small, horn-coloured speck. This total destruction of the globe of the eye generally insures the safety of the other, and renders it less liable to be affected by future attacks of inflammation. When one eye is lost by styphyloma, and the other remains useful, it is well to do what nature has left undone, and, instead of attempting to reduce the sac by puncturing it, at once to lay it open and extract the lens."

The account here given by Dr. Vetch is calculated, in an eminent degree, to impress on the mind of the student the importance of this disease; he is not, however, to expect to meet with it in this form in daily practice. He will not always have an opportunity of observing the first symptoms of the attack, as the patient seldom presents himself until the complaint is fully established, and he will not often find the symptoms so rapid in progress or violent in degree. The practitioner, in studying an individual case, has before him the vascularity, tumefaction, scalding pain, and purulent discharge in the severest form. His first consideration should be to recall to his memory the dangerous consequences which he is called on to avert, and which constitute the prominent symptoms of the disease. In the first or inflammatory period, he is to recollect that the eye may be lost by sloughing or abscess of the cornea, or by suppuration of the whole eye-ball; in the second stage, he has to apprehend the injury or destruction of the cornea from ulceration, or that change of organization of the conjunctiva which proceeds to permanent increased vascularity, and that peculiar condition denominated granular lids. The nature of the pain experienced by the patient should receive particular attention: if it be the characteristic scalding sensation of sand beneath the lids, it is indicative of severe conjunctival inflammation only, but if this be accompanied by intense aching, extending to the temples and sides of the head, it is evidence of the extension of the inflammation to the eye-ball itself; the cornea and fibrous sclerotic refusing to yield to the distension of inflammatory action, like muscular fasciæ and the coverings of joints under similar circumstances.

As sloughing or abscess of the cornea is the consequence most to be apprehended during the inflammatory period, the practitioner watches with anxiety for any appearance indicative of this evil. It is not perhaps possible to detect the first change which the cornea undergoes in this process, but when this transparent structure assumes a dirty white opaque appearance, either wholly or partially, the mischief is easily recognised; and when subsequently the sphacelated portion comes to be cast off by the usual process of ulceration, and exhibits a line of separation between the dead and living parts, no doubt of the nature of the injury can be entertained. Abscesses in the structure of the cornea are also liable to occur during the inflammatory period, and have probably been often confounded with the sloughing here described, the distinction being difficult, and the two destructive consequences sometimes being combined, and constituting a condition analogous to common anthrax. Abscess of the cornea is peculiar in this respect, that it does not appear to consist of a distinct sac of purulent matter, but merely a deposit in the cellular or laminated structure of the cornea; it consequently does not open at one point and discharge its contents, but breaks into an open ulcer, not easily distinguished from the broken surface of a slough. The colour of the opacity of the cornea constitutes the best criterion; if the spot be of the usual straw-coloured tint of purulent matter, and not the dull, dirty white of dead macerated cornea, abscess, not slough, is the process in progress. Abscess, also, probably occurs more frequently in circumscribed spots, and seldom extends to the entire circumference of the cornea. The secretion of purulent matter in the chamber of the aqueous humour is easily distinguished from abscess of the cornea at its commencement, by the purulent matter falling down in the aqueous humour between the iris and cornea, and by its surface assuming a horizontal level, repeatedly described under the title of *hypopion*, *onyx*, or *unguis*; but when the whole chamber is filled with pus, and the cornea consequently presents a uniform yellow appearance, the real nature of the appearance is not so obvious.

Causes.—In every day practice, where the cases are comparatively few, the inquiry into the cause of the complaint is not so important as when numbers of persons collected together are violently attacked; because the occurrence of a few instances of the disease would not justify the adoption of preventive measures by a large community, which are imperatively called for where it rages among smaller numbers more crowded together, as in barracks, schools, and ships. That any cause producing irritation of the conjunctiva,—as strong light, currents of cold air, or the contact of dust blown through the atmosphere,—or any cause usually producing inflammation of mucous membranes,—as sudden transitions from heat to cold, or peculiar conditions of the atmosphere,—is likely to produce purulent ophthalmia, can scarcely be denied; but the extent to which these causes operate, or the circumstances under which they become influential, have not been ascertained. The occurrence of the disease in particular countries, and in barracks, schools, and ships, is notorious; but the real causes of such occurrence have not been satisfactorily determined.

The rapid extension of the disease among the individuals of crowded communities has naturally led to the belief that it is contagious, and not only communicated by actual application of the discharge of a diseased eye to a sound one, but even through the medium, whatever it may be, by which diseases notoriously contagious are transmitted. The discussion respecting the contagious nature of the affection is involved in the same difficulties and contradictions which embarrass the inquiry into the nature of contagion in general: sufficient facts, however, have been adduced to justify the separation and removal of communities among whom the disease breaks out, and to induce the prudent practitioner to enjoin the greatest attention to the prevention of contamina

tion by actual contact of the matter of the disease with the eyes of those not affected by it.

Prognosis.—The prognosis in severe purulent conjunctival inflammation must obviously be most cautious. The patient should be made fully acquainted with the immediate danger of destruction of the organ to be apprehended from sloughing or suppuration, as well as the prospect of slow and doubtful recovery in consequence of the great alteration or disorganization of the conjunctiva produced by the intense inflammatory action. In forming his prognosis, the practitioner must of course be guided by the degree of violence of the attack, the habit and constitution of the patient, and the experience he has had as to the modification of the disease by climate or other circumstances.

Treatment.—In severe conjunctival inflammation the principles inculcated in the commencement of this article should not be overlooked. The resources available for arresting the inflammatory action are, as has been observed, bleeding general and local, emetic and nauseating medicines, purgatives, diaphoretics, and, according to some, mercury. Locally, astringent, sedative, stimulant, cold or warm applications, and occasionally blisters, scarifications, and other remedies directed to peculiar conditions, must be resorted to. Before the practitioner makes up his mind respecting the value of bleeding in this disease, he should pause to consider the effect of this depletion in arresting inflammation of mucous membranes generally; and having done so, he will probably be prepared to admit that in many cases the lancet is not so valuable a resource as might be expected, or as it is found to be in inflammation of serous membranes or other structures. The advantage of bleeding in croup cannot be denied, but it is to be recollected that this disease is more liable to terminate in effusion of coagulable lymph than in secretion of purulent matter. Catarrhal inflammation of the lining membrane of the nostrils or the trachea and bronchial tubes, and dysentery in the acute form, are treated by bloodletting more with the view of diminishing the febrile symptoms than with the hope of cutting short the local inflammatory action. Bleeding will not cure conjunctival inflammation, but it is a most valuable auxiliary means of relief, by reducing the part to a condition in which other remedies become more effectual. The writer has seen the abstraction of blood carried to the greatest extent possible, consistent with the safety of the patient; he has seen repeated bleedings of forty, fifty, and even sixty ounces, and streams flowing from the arm and temporal artery at the same time, without generally beneficial results. More moderate bleedings, suited to the intensity of the symptoms, habits, and constitution of the patient, should, however, form part of the treatment. It is scarcely necessary to say that persons emaciated by want, enervated by drunkenness and debauchery, or debilitated by respiration of impure air, are not fit subjects for a system of depletion; on the contrary, such treatment is most destructive to them, and the very reverse of it is demanded.

The means by which blood should be removed, or the sources from which it should be drawn, deserve consideration. Many prefer opening the temporal artery, from a theoretical notion that by emptying one branch of an artery, those ramifying from the same source have the force of their currents diminished; but it never has been proved that this is actually the case, and it may even be doubted that any advantage is derived from the preference, while much inconvenience, irritation, and heat is produced by the bandage required to secure the wounded vessel. If advantage be derived from a local diminution of the circulating fluid, it may more reasonably be expected from opening the jugular vein; because in this case this vessel cannot, like the temporal artery, be instantly refilled by the heart's action: therefore, when the size of the vein, the formation of the patient, and other circumstances are favourable, this vessel should be selected. Bleeding in the arm, however, from its greater convenience, and the ease with which it may be performed, is generally preferred, and perhaps in the majority of cases without disadvantage to the patient.

The local abstraction of blood by leeches or cupping is the next resource, after the effect of the general depletion has been ascertained; it may be resorted to in the evening if the general bleeding took place in the morning, or, according to the urgency of the symptoms, may be postponed till the following day. Twelve, eighteen, or twenty-four leeches should be applied to the temple or over the cheek-bone, so as to leave an opportunity of stopping the bleeding by pressure should it become necessary. The irritation, inflammation, and tumefaction produced by the application of leeches to the swollen eyelids more than counterbalances the good, if any, derived from emptying the vessels of the inflamed part. The advantage from the bleeding by leeches appears to depend upon the continued trickling of blood, which is perhaps best encouraged by the application of compresses of old linen wrung out of warm water and removed and replaced every ten minutes, or as often as they become soaked with blood. The application of a few leeches to the conjunctiva of the lower lids has latterly been recommended and practised, and may perhaps be resorted to with safety and even advantage in the after stages of the disease; but in a case of violent purulent ophthalmia threatening destruction of the eye, the effect is too inconsiderable to risk any aggravation of the inflammation by the leech-bites.

Local abstraction of blood from the inflamed conjunctiva by scarification has been practised from the most remote periods; the same objection may be made to it as is offered to the application of leeches, that is, the small quantity of blood drawn, and the great extent of injury inflicted. When the chemosis or vascular tumefaction of the conjunctiva is very great, and the membrane projecting between the lids or overlapping the cornea, the writer, in place of merely scarifying or scoring the surface, runs an extracting knife from one end to the other of the tumour, by which the effused serum is allowed to escape, tension is relieved, and generally a considerable quantity of blood discharged. From this practice advantage is frequently derived without any injurious consequence either temporary or permanent.

As it is of the utmost importance that the practitioner should be informed as to the value of

bleeding in this disease, the opinions of Dr. Vetch, Mr. Lawrence, and Mr. Guthrie, are here subjoined. Dr. Vetch observes, "A perfect command over the disease depends less on lowering the system than on the temporary cessation of arterial action by the syncope, which it becomes the object of the operation to produce. This practice, besides its efficacy, will accomplish the cure with a much less expenditure of blood than is occasioned by the repeated bleedings generally had recourse to, where this method of rendering one equal to the cure of the complaint has been neglected. Sometimes, before the approach of faintness, the redness of the conjunctiva for the most part disappears; but this is no security against the return of the disease, if the flow of blood be stopped without deliquium animi succeeding." And again, (page 217, Treatise on Diseases of the Eye,) "Of three thousand cases admitted into the ophthalmia depôt, I am not aware of any one in which the practice of depletion, assisted by the remedies mentioned, did not prove effectual when the patient was received under the first attack of the disease." He then states that twenty-five men only were lost to the service of all those admitted into the ophthalmic depôt; "but an unfortunate feature of this very dreadful complaint is its great tendency to recur, even after the eye has recovered its healthy and natural appearance; and although it be in our power to conquer its present violence, no treatment can prevent relapses from taking place. As long as the lining of the palpebræ continues villous, this accident is liable to recur, with all the severity of the original attack." From this last observation it is to be suspected that numbers of these men were discharged as cured when labouring under pulpy and villous conjunctiva, subsequently proceeding to granular lids and opaque cornea; especially when it is known that thousands were lost to the service notwithstanding the prevalence of the bleeding practice.

Mr. Lawrence (Lectures, reported in the Lancet,) says, "The first measure is to take blood from the arm, and this in large quantity, so as to produce syncope: you may expect to derive much more benefit from one bleeding of this kind than from the repetition of smaller ones. It may be necessary to repeat the venesection; and if the symptoms should remain urgent, you must not hesitate to do it: you may subsequently take blood by cupping from the temple, and apply numerous leeches about the eye." In his account of gonorrhœal ophthalmia, bleeding is still more strongly recommended.

Mr. Guthrie (Lectures, reported in the Medical and Surgical Journal,) states, "It was deemed necessary to abstract blood in large quantities; indeed sixty, eighty, and even one hundred ounces have been drawn. It was often thought necessary to re-leech the eye and blanch the countenance to effect a cure, and I have no doubt that it has been done with success; and the extreme vessels of the conjunctiva have been so drained as to be rendered incapable of going on with the secretion. Those who find fault with this practice in all probability never saw the disease; for it is the most efficient mode of proceeding, and the best when there are no local means employed."

After the requisite depletion by the lancet, the practitioner avails himself of the other resources within his reach. If there be reason to believe that there are crudities in the stomach, with foul tongue and headach, an emetic may be administered with advantage; and when the nausea subsides, the bowels should be freely opened, and the discharge kept up by the administration of suitable medicine at proper intervals. A few grains of calomel at night, followed by repeated doses of the common mixture of infusion of senna and sulphate of magnesia in the course of the following day, may probably answer every purpose. From the advantage derived from nauseating medicines in other forms of inflammation, similar advantage has naturally been expected from its administration in purulent ophthalmia; but in consequence of their not answering the exaggerated expectations of the practitioner, they have not, perhaps, been resorted to to that extent they deserve. The effect may be advantageously secured by the addition of tartar-emetic to the purgative mixture, or the same medicine alone in solution may be given after the bowels have been freely opened, in doses sufficient to produce slight nausea, and secretion from the skin encouraged at the same time by confining the patient to bed. Tobacco has been resorted to for the purpose of exciting nausea; but experience has not yet proved that it possesses any superior advantage, while we are less familiar with its effects than with the preparations of antimony. Mercury has been recommended and resorted to for the removal of conjunctival inflammation, but with little success. The opinions of Mr. Lawrence, Beer, Delpech, and others, are unfavourable to the practice. Without accomplishing any valuable object, it reduces the patient to the condition which is most calculated to perpetuate the destructive change in organization of the conjunctiva.

Whatever importance is to be attached to the opinions of English writers on the present subject—respecting the paramount value of bleeding and low living in the treatment of the disease, the Irish practitioner must undoubtedly be circumspect, in this respect, in his treatment of the poor. It may be very well to bleed and otherwise reduce those who have been well fed and have enjoyed all the comforts of life; but the practice is utterly inadmissible in a country where the poor are abandoned to a state of destitution, and, if not absolutely starved, are so ill fed, and clothed, and lodged, that frequently no healthy action can be roused until the constitution be invigorated. In Dublin it is often absolutely necessary to place a patient, a few days after the first attack of purulent ophthalmia, on full diet, consisting of animal food with ale or porter, accompanied by the administration of bark or other tonics.

In the treatment of purulent ophthalmia the management of the patient, with respect to the temperature, ventilation, and lighting of his apartment, should not be overlooked. The practice of immuring a patient in a close room, with windows shut and curtains drawn, and with the addition of an enclosure of curtains round his bed, involving him in a contaminated atmosphere loaded with the excrementitious effluvia of his body, is most pernicious. The close, stinking, crowded, and darkened ward to be found in some hospitals, called

the eye-ward, is equally destructive. The author of this article has almost daily opportunities of witnessing the refreshing and salutary effects of what may justly be called a meal of fresh air, on persons subjected to such treatment; and he invariably finds that patients obliged to go out of doors are more easily managed, and escape with less injury, than those confined in the way just mentioned.

With respect to this part of the treatment, Dr. Vetch makes the following observations:—"I entertain so favourable an opinion of the effects of the free exposure to the atmosphere, that although no person can better appreciate the importance of decisive measures in the early stage of the disease, I would in favourable weather risk the delay of a journey on foot or horseback, or in a carriage, or a voyage by sea, provided the eye be freely exposed to the air. Even when the second stage has commenced, by the appearance of a chemosis and purulent secretion, I have never seen any other than the best effects to attend a change of place. Soldiers who have commenced a march with the disease completely formed, though exposed to heat, dust, and fatigue, and not abstaining even from intoxication, are invariably better at the end of the journey than when they set out. The instances of this fact which I could adduce from my own observation are innumerable; and I am informed by Mr. Murray, surgeon to the forces, that so strongly did he observe the beneficial effects of exposure to the air, when a great number of men affected with the disease was sent, under his care, to the interior of Sicily, that he was induced to march them from one place to another, with a view solely to the good effects he saw resulting from it."

In considering the local treatment of severe purulent ophthalmia, the first and most important point to be determined is the value of powerfully stimulant or astringent applications made directly to the inflamed conjunctiva in the first or inflammatory stage of the disease. The great advantage of strong astringent solutions in arresting the progress of that disorganizing change which follows violent conjunctival inflammation is undeniable; but it requires much circumspection to avoid confounding the advantages derived from astringents in the chronic stage with those derived from similar applications in the acute. The question to be determined is, whether a powerful stimulant or astringent, as ten or twenty grains of nitrate of silver in an ounce of water, or ten grains in a drachm of lard, can be with safety and advantage applied to the surface of the inflamed conjunctiva in the first attack of violent purulent ophthalmia. When a patient presents himself in the first stage of purulent ophthalmia, with severe scalding pain, and with the conjunctiva in a state of chemosis, overlapping the cornea and projecting between the eyelids, few practitioners will feel inclined to soak the eye in a ten grain solution of nitrate of silver, or thrust a portion of the ointment (ten grains to the drachm) between the lids and the swollen and turgid conjunctiva. The most strenuous advocates for the stimulating practice inculcate the necessity of allaying inflammatory action before or during its adoption. Whether incipient purulent ophthalmia of the character now under consideration can be at once cut short or not by the application in question, has not yet been established to the full satisfaction of practitioners. The circumstances under which the experiment may be made to enable the observer to arrive at a just conclusion seldom occur, because he rarely meets a case in its very onset which he can pronounce to be violent purulent ophthalmia, the severe characteristic symptoms not being yet developed. If purulent ophthalmia rages in a regiment, a school, or a ship, and the surgeon, watching narrowly the symptoms of the accession of the disease, applies this stimulating astringent to the surface with decided effect; or if a patient in the hands of a practitioner for the treatment of gonorrhœa presents the symptoms of conjunctival inflammation, and is similarly treated with similar good effects, the question must be determined in the affirmative. Several military surgeons, who have enjoyed the best opportunities of observing and treating the disease, are decidedly favourable to the practice.

Mr. Lawrence, however, in his book on Venereal Diseases of the Eye, speaks of it with caution and reserve. After quoting the authority of Mr. Melin, Mr. Bacot, Dr. Ridgeway, and Dr. O'Halloran, on this subject, he observes, "I have not seen purulent ophthalmia, whether ordinary or gonorrhœal, treated on this plan; nor am I aware that any case of the latter kind is recorded. Destructive or injurious consequences have so frequently resulted under the usual management of this disease, that I should certainly employ the local astringent if I met with a case favourable for the trial; that is, where the affection had not extended beyond the conjunctiva. Bloodletting might be resorted to at the same time. In most cases, however, our aid is not sought until the cornea has become affected; and it is, therefore, too late for the astringent plan." In a note he adds, "Since the statement in the text was written, I have employed the caustic solution in two cases of conjunctival inflammation with the best result. One of these was mild gonorrhœal inflammation. The other was catarrhal inflammation of the membrane, affecting both eyes of a gentleman who had been convalescent from gonorrhœa for a few weeks. As he was a person of robust make and full habit, and the eyes were very red and stiff, I took three pounds of blood from the arm, and purged him freely, with relief of the local symptoms, which were completely removed by a subsequent application of the caustic solution."

The practice here alluded to is advocated so strenuously by Mr. Guthrie, that it is desirable to have his opinions conveyed in his own words. The following extract is, therefore, made from his lectures reported in the Medical and Surgical Journal. "In the more formidable affection which runs its course in three or four days, neither the nitrate of silver in solution nor the vinum opii are effective; it requires a more powerful local application. The disease begins externally, and is a local disease of a peculiar character. If we can set up a new action, or alter that which is going on, we check the original affection, according to the principle of John Hunter, that no two diseases or actions go on at one and the same time.

Acting on this principle, I took the nitrate of silver in substance, and made it into an ointment. I did not arrive at its exact composition at once, but gradually acquired it by degrees; it was made at various times, of five, six, ten, and twenty grains to the drachm; and after trying all these different preparations, I came to the conclusion that the ten grain ointment was the best. Take half a drachm of the salt, and powder it in a glass mortar, then sift it through a bit of muslin, so that it is reduced to an impalpable powder, for if there are any grains left, they will stick in the cornea, or in the folds of the conjunctiva, and produce a slough. Ten grains of this impalpable powder should then be thoroughly incorporated with a drachm of hog's lard, on a glass slab with an ivory paper-cutter; and in order to ensure proper attention in the preparation of this ointment, I sought for something to mix with it, which would require some time for its incorporation, and selected the liquor plumbi acetatis for this purpose. Fifteen drops are to be duly mixed with the ointment; and as it generally requires some minutes to do this, there is reason to believe that the trituration is complete. There has been, as usual, some dispute concerning this ointment; the first thing said was that it was violent and useless: well, that has been got over. The second stage was to attribute the introduction of it to some other person. The third to alter the composition, and instead of the liquor plumbi acctatis to mix opium, &c. with it. I have no objection to this, if the gentlemen will only leave me the principle, which is all I contend for. I care not if they change all the component parts, or whether they apply it by a brush of the little finger, or the probe. It has been said that it is soon valueless and inert. All I can say is, let those who think so have it applied to their eyes, and they will soon change their opinion, even if it be a year old. Before the ointment is applied in this purulent inflammation, the discharge must be well cleansed out by a solution of alum; then the ointment having been inserted, the lids must be moved freely up and down so that the whole conjunctiva gets its due proportion of ointment, and this is shown by its turning white. If it does not turn white, it has not been sufficiently applied, and will not answer the purpose; if we wish to be quite sure, we turn out the eyelids, and rub the ointment on them; this application gives pain, which lasts for half an hour to an hour, or more; it is not quite so acute as the vinum opii. I had rather that the pain should last an hour or more, as the action going on is more likely to be changed. When I apply this ointment, I generally direct the patient to lose blood, not to the amount of sixty ounces, but to about twenty, and I had rather that he should faint: and I do this because the application will only alter the action in the extreme vessels, and not that which is behind them in the ball itself, and it is therefore necessary to diminish action in them by bleeding. If, however, the inflammation is moderate, I do not bleed at the time, leaving directions that if the patient is not better in the evening, or the next morning, blood should then be taken. Warm narcotic fomentations may be employed to relieve uneasiness, and opium should be given to allay pain and obtain sleep, while a solution of alum, half a drachm to half a pound, should be injected from time to time in the eye to clear it; but should the patient sleep, he must not be disturbed. A mild ointment may be applied to the lids at night, to prevent their adhering together. The next morning the discharge is again to be removed, and the ointment re-applied, for on no account should the action we are desirous of exciting be suffered to cease; the other remedies are likewise to be continued. In addition to these I would give calomel and opium, so as to affect the mouth, and the other more common remedies; and rest and diet should be attended to. When I hear of twenty or thirty persons losing their eyes from this disease, I say that it must always be so, unless they are treated on this principle, bearing in mind that some diseases in certain persons are incurable from the first, and that no one means of cure is applicable to every case. I am certain, however, from experience, that the plan I have recommended is the most generally efficient and certain of any that has hitherto been advised, whilst it is also less injurious to the constitution."

There is much difference of opinion as to the comparative value of cold or warm applications in the acute stage of purulent ophthalmia. Either in ophthalmic or any other local inflammation, the advantage to be expected from cold applications is the reduction of the temperature of the part, and consequent diminution of vascular action; but this object is very rarely obtained, and the real effect of cold in abating inflammation has as yet scarcely been ascertained. The attempt is made in conjunctival inflammation by repeated applications of cloths wrung out of cold water, but these cloths become so speedily of the same temperature as the part, that nothing more is effected than a temporary cooling, followed by perhaps greater heat and vascular reaction. To obtain the advantages to be expected from cold applications, these cloths should be changed by a nurse, sitting at the bedside of the patient, twice in a minute, or a fold of old linen may be laid across the eyes with the ends hanging into cups on each side, and cold water squeezed on with a sponge, or allowed to drop from a vessel contrived for the purpose. In this way the application of cold as a remedy in ophthalmic inflammation, and especially from wounds or other injuries, is undoubtedly of value, although many patients prefer the effects derived from warm moisture. The following objections made by Mr. Travers to cold applications, in his Synopsis of Diseases of the Eye, are perhaps more applicable to their maladministration. "Although the sensation of cold is most agreeable to an organ under acute inflammation at the moment of its application, it is generally followed by increase of heat and pain; and in familiar instances the pulsatile action of the vessels leading to an inflamed part is so increased as to evince its stimulating effect, and the reaction thereby induced. When, however, the acuteness of the inflammation has subsided, and the sensibility of the part is in proportion diminished, the effect of cold is only tonic, and has a salutary tendency to restore the balance of the circulation. I therefore decidedly prefer a tepid application in the painfully acute stage of inflammation." With the reservation that cold properly applied is not to be des

pised, this advice is good for the purposes of general practice.

Warm applications may be made by stupes, poultices, or light compresses, all of which are generally mismanaged, and frequently do more mischief than good, unless particularly attended to by the practitioner himself. The stuping is generally attempted by wringing a flannel cloth out of a hot decoction of chamomile or poppyheads, and laying it across the patient's eyes, in which case the steam is dissipated, and little of it comes in contact with the eyes. It is best accomplished by the patient himself, who, sitting up in bed, should receive a small piece of flannel, wrung out of the hot water, from the nurse, and hold it in the hollow of his hands under the eyes, changing it as it ceases to give out steam. Many little contrivances may be made for the purpose with sponge or other materials, but holding the eyes over vessels of hot water, or exposing them to steam extracted from a boiling apparatus contrived for this purpose, is not found advantageous, as the heat applied is generally too great. Whether any benefit be derived from the addition of sedative or other medicinal ingredients to the stupe, remains to be proved: it is not, however, attended with disadvantage, and a medical man of any sagacity will see the necessity of yielding to prejudices for the attainment of objects directed to the relief of his patient. If the practitioner determine to add opium to the stupe, he should give the patient the advantage, whatever it may be, of its efficient application, which is, perhaps, obtained in a neater and more perfect manner by the addition of a drachm of the tincture, or a few grains of the watery extract to a pint of hot water.

Whatever difference of opinion may exist with respect to the extent to which stimulating or astringent applications should be employed in the inflammatory stage of conjunctival inflammation, there is little doubt entertained of the value of astringents in the chronic stage, or that condition of the conjunctiva which may be considered the necessary consequence of the violent inflammation above described. The salts most commonly used for this purpose are acetate of lead, alum, sulphate of copper, sulphate of zinc, corrosive sublimate, and nitrate of silver. Notwithstanding the length of time these salts have been in use, it does not appear that any conclusive experiments have been made to ascertain their comparative value, or the best proportions in which they should be used. The practitioner has little more to guide him in the selection than the vague and uncertain evidence of expressions of confidence in some one or other by different practical writers. The most generally valuable, safe, and efficient, are the acetate of lead, alum, and nitrate of silver, the sulphates of copper and zinc being more stimulating and irritating, with less astringent properties. Weak solutions, however, of sulphate of zinc or copper are unquestionably of value in the slighter vascularity of the conjunctiva following catarrhal ophthalmia, or arising without preceding inflammatory action. Saturated solutions of acetate of lead or alum may be used with the greatest safety, and without producing any such effect as follows the introduction of other salts. Saturated solutions of sulphate of zinc may also be applied to the conjunctiva without any other destructive consequence than a temporary increase of vascularity, pain, and weeping; but a saturated solution of sulphate of copper produces violent inflammation, probably acting chemically, and producing superficial destruction of the surface. Nitrate of silver, in the proportion of ten or fifteen grains to the ounce, appears also to act chemically, causing whiteness of the vascular conjunctiva, but without the irritating and stimulating effects of sulphate of copper. Nitrate of silver, even in the proportion of three or four grains to the ounce, if used for a month or six weeks, will produce an olive-coloured indelible stain of the conjunctiva, and lamentable deformity; or both it and acetate of lead, applied while ulcers of the cornea exist, produce the worst form of opacity by being decomposed by the tears and deposited on the flocculent surface, and there detained until permanently fastened by cicatrization, as has been described by the author of this article in the Dublin Hospital Reports. None of these disadvantages attend the application of the alum solution, and its powerfully astringent qualities are undeniable. The condition of the conjunctiva to which the reader's attention is called with reference to these applications, is that which exists from a fortnight to six weeks after the first attack, when the acute inflammatory symptoms have subsided, and before the membrane has acquired the extreme condition of disorganization denominated granular conjunctiva. In this state a solution of from five to ten grains of nitrate of silver in an ounce of water, or the ointment recommended by Mr. Guthrie, will prove of great advantage; but the practitioner should not allow the praises exclusively bestowed upon it to induce him to discard the saturated solutions of alum or acetate of lead, as he may be assured that they will often be found preferable in practice, although the particular condition in which they are so may not have been ascertained. The effects of the saturated solution of acetate of lead, when such cases, modified by scrofula, are accompanied by vascularity of the conjunctiva covering the cornea, are frequently most remarkable. Dr. Vetch expresses the following opinion respecting the solution of acetate of lead. "The liquor plumbi acetatis in its undiluted state is the application which I can recommend as the most efficacious, and at the same time incapable of doing harm in this, and in every stage of purulent ophthalmia. The sensation it occasions is that of some dust or sand having got into the eye, which lasts from ten to twenty minutes; there is generally a copious lachrymation, and the eye afterwards feels cool, and the sight is clear."

Whichever of these solutions is preferred should be fairly dropped into the eye, after it has been cleansed with sponge and warm water, on awaking in the morning, and the patient should remain quiet with the lids closed for half an hour. This may be repeated in the evening, if not found to produce increase of pain or irritation, and the patient should be allowed a weaker solution to wash the eyes with more frequently in the course of the day. At night the edges of the lids may be smeared with cream, fresh butter, or some mild ointment. On the continent a compound salt, called the *lapis divinus*, is much used; it is made

by heating eight ounces of nitre, alum, and sulphate of copper in a crucible, and, when fluid, adding half an ounce of camphor, and closing the vessel until cold. It is used in the proportion of three or four grains to the ounce and appears to have the same effect as the sulphate of copper.

The application of the vinous tincture of opium was first recommended by Mr. Ware, in his "Remarks on the Ophthalmy." He gives the following account of the method of applying it, and its effects: "I would particularly recommend the thebaic tincture of the old London Dispensatory; a medicine composed of opium and warm aromatics, dissolved in mountain wine." "When first applied, it causes a sharp pain, accompanied with a copious flow of tears, which continues a few minutes, and gradually abates, after which a greater and remarkable degree of ease generally succeeds. The inflammation is often visibly abated by only one application of this tincture; and many bad cases have been completely cured by it in less than a fortnight, after every other kind of remedy had been used for weeks, and sometimes months, without any success. But this speedy good effect is not to be expected in all cases indiscriminately. In some, the amendment is more slow and gradual, requiring the tincture to be made use of for a much longer time; and a few instances have occurred, in which no relief was at all obtained from its first application. In cases of the latter kind, in which the complaint is generally recent, the eyes appear shining and glossy, and feel exquisite pain from the rays of light. However, notwithstanding these symptoms, the application is sometimes found to succeed; and whether it will or not, can only be determined by making the trial, which is attended with no other inconvenience than the momentary pain it gives. When it is found to produce no good effect, the use of it must be suspended, until evacuations and other proper means have diminished the excessive irritation; after which it may again be applied, and bids equally fair for success, as in those instances in which it never disagreed. If two or three drops of the thebaic tincture are dropped at once on the globe of the eye, the pain they occasion will be considerably greater than if they are placed in the inner angles of the eyelids, and made to glide gradually on the eye, by gently drawing down the lower lid. At the same time that this latter mode of applying the tincture is much less painful than the former, I have found, in a great variety of cases, that it is equally beneficial." Experience has fully established the character here given by Mr. Ware of the vinum opii; it is, however, most applicable in those cases where there is much scalding pain, lachrymation, and intolerance of light.

If the pulpy villous vascularity produced by the inflammation above described be neglected, or be not removed by the applications alluded to, it degenerates, in about six weeks or two months, into a still more destructive condition; the conjunctiva lining the lids acquiring a rough irregular vascular appearance, which, from its resemblance to the granulating surface of a sore, has been named the granular conjunctiva. This condition, if not altered or removed, is followed by red vascularity and opacity of the conjunctiva covering the cornea, and almost total loss of vision. To remove this state of the membrane, the resources of ophthalmic surgery have been nearly exhausted, and frequently without effect. It even unfortunately happens that the destruction or removal of these warty prominences or granulations is not followed by recovery. In fact, the organization of the conjunctiva is destroyed by the severe inflammation, and, if ever restored, requires a great length of time to return to its original condition. These granulations may be removed either by the knife or escharotics, and the question respecting the preference to be given to either method has been the subject of much controversy. They certainly may be shaved off by the dexterous use of a small scimeter-bladed knife, and their removal in this way is accompanied by the advantage of local bleeding, and consequently less subsequent pain, irritation, and inflammation, than attends the use of escharotics. The partial use of escharotics, however, is often necessary to complete the removal, as it is impossible to reach all the granulated surface with the knife. The escharotics commonly employed are the nitrate of silver, or sulphate of copper, in substance. The former is preferable, its effect is more decisive, and the inflammation and irritation, from its application, are less: the latter is, however, preferred by some.

The operation of applying the escharotic must not be carelessly performed. Much mischief has been frequently done by allowing an inexperienced pupil to rub the inside of the lids with a piece of sulphate of copper in a slovenly manner. The upper lid should be everted, and the surface dried with a cambric handkerchief; the whole of the granulations should then be repeatedly touched with a pencil of nitrate of silver until the surface becomes of a deep ash colour; it should then be carefully washed with a plentiful stream of water from a syringe, lest any particle of nitrate of silver should adhere undecomposed, and be turned in on the cornea. If the sulphate of copper be used, it will require a more continued application to produce the escharotic effect, and the washing must be performed with equal care. The application of the escharotic must be repeated as often as the granulations are observed to remain after the surface becomes clear from casting off the coat produced by the nitrate of silver.

[In chronic granular ophthalmia, Dr. Hays (see his edition of *Lawrence on Diseases of the Eye*, p. 267, Philad. 1843,) has found a saturated solution of the chloride of sodium contribute more to the cure than any other application. When the eye is irritable, with injection of the conjunctiva of the ball and lachrymation, he knows of no remedy that effects such prompt and marked relief.]

Ointments are frequently resorted to for the removal of the vascularity and tenderness of the lids, produced by purulent ophthalmia, especially where the skin at its meeting with the conjunctiva becomes red and destitute of cuticle, constituting lippitudo, a condition which, it is to be recollected, arises often without preceding acute inflammation. Where the object is merely to obviate the inconvenience arising from the dryness produced by exposure to the air, or the scalding from contact of the tears, it may be accomplished by the appli-

cation of a little cream, fresh unsalted butter, or the spermaccti ointment. It is often, however, necessary to combine astringent or stimulating ingredients with the ointment. The ointment of nitrate of mercury, diluted with five or six times its weight of oil or lard, is very commonly used, and frequently with good effect, if continued for a few days only. The stimulating effect appears to be salutary as a first and temporary impression, but when persevered in for a length of time, seems to have a contrary result. The ointment of oxyd of zinc is a very safe and efficient astringent application, as is also the mixture known as the ophthalmic ointment of *Janin*, composed of four drachms of lard, two of tutty or impure oxyd of zinc, two of Armenian bole, and one of calomel. These ointments should, however, be made with such a proportion of oil as will give them so soft a consistence that they can be applied with ease to the lids with the point of the finger or a camel-hair pencil; they should also be properly and carefully ground on a flag with a muller, not merely mixed on a tile with a palate-knife, and great care taken that the oily ingredient be not rancid or burned. Ointment of acetate of lead, or a mixture of oil or lard, with liquor subacetatis plumbi, is another application frequently employed with advantage. As oily applications are sometimes found not to agree with the surface, the practitioner may find it necessary to combine astringents with some tenacious ingredient of a different description; for this purpose, clarified honey may be used, with the addition of alum or Armenian bole, finely levigated. Honey alone will often afford relief in the slighter degrees of vascularity following conjunctival inflammation.

In the treatment of purulent ophthalmia the advantages to be derived from blisters should not be overlooked. The extent to which they may prove beneficial in any particular case can perhaps scarcely be ascertained; but as their value generally in contributing to the removal of local inflammation is admitted, it is not reasonable to disregard such a resource. These may be applied at any period of the disease, but they probably are more efficacious after the more acute symptoms have subsided, or before they have set in, and appear most indicated where there is much irritability, intolerance of light, and scalding lachrymation. They should not be applied too near the eye, as in such case the cutaneous inflammation sometimes spreads to the lids and increases the mischief. A patch of the scalp from the temple to the top of the ear should be shaved, and a blister of size sufficient to secure a decided counter-irritating effect, applied and allowed to remain on until the skin is fully inflamed. A scrap of blister behind the ear does not produce sufficient impression to compensate for the annoyance it occasions to the patient.

Gonorrhœal Inflammation of the Conjunctiva.—Mr. Lawrence, from whose valuable work on venereal diseases of the eye it will be necessary to make copious extracts in treating this subject, considers that there are two varieties of gonorrhœal inflammation of the conjunctiva, the acute and mild. The acute gonorrhœal ophthalmia is perhaps to be considered specifically distinct from the common severe purulent ophthalmia, on account of its origin and consequences, rather than from any decided difference in the character and symptoms of the disease. There is the same scalding pain, intense vascular chemosis, profuse purulent discharge, sloughing, abscess, and ulcer of the cornea, and permanent disorganization or granulation of the conjunctiva, observed in the Egyptian and other severe forms of purulent ophthalmia. Mr. Lawrence says, "the local symptoms are not sufficient to establish a distinction between this affection and common purulent inflammation of the most violent kind, and its peculiar nature is indicated by the concomitant circumstances, that is, by the preceding or existing gonorrhœa." He considers, however, that it generally attacks only one eye, while common purulent ophthalmia affects both; that it commences in the conjunctiva of the eyeball oftener than in that of the lids, that the symptoms are more violent, and that its progress is more rapid.

Notwithstanding the similarity of symptoms between the severe purulent and the gonorrhœal ophthalmia, a repetition of the account of those symptoms as they occur in the latter in the words of Mr. Lawrence may not be unacceptable. "There is the greatest degree of vascular congestion, the most intense and general external redness; excessive tumefaction of the conjunctiva; great chemosis, with corresponding swelling of the palpebræ; and profuse yellow discharge. In the first stage of the disease, which is short, the inflammation is confined to the conjunctiva, and is attended with soreness and stiffness, with the sensation of sand or dirt in the eye, and with more or less uneasiness on exposure to light or using the organ. The affection soon extends to the cornea, with severe and agonizing pain in the globe, orbit, and head, augmented to intolerable suffering on exposure to light, and with febrile disturbance of the system of inflammatory character. The danger to the organ is now most serious and imminent; and indeed, when the disease has thus advanced from the mucous membrane to the globe itself, we can hardly expect by any kind of treatment to avert entirely its destructive consequences. The violent inflammation, which causes the yellow puriform discharge from the mucous surface of the conjunctiva, produces effusion into the cellular texture connecting it to the surrounding parts. Hence the general swelling of the membrane, and that more considerable tumefaction on the front of the sclerotic, round the cornea, which is called chemosis. The latter is often so considerable that the swelled conjunctiva overlaps the cornea all round, so as nearly to hide it. Similar effusion takes place into the cellular texture of the eyelids, enlarging them considerably, more particularly the upper, which hangs over and completely covers the lower. The palpebral swelling is sometimes œdematous, with the integuments but little redder than natural; in other instances it is firmer, with the skin, particularly of the upper eyelid, bright red. The latter state denotes more active inflammation, and greater danger to the organ. The chemosis and the swelling of the lids make it often difficult, and sometimes impossible, to get a clear view of the cornea. Although it is desirable to do this, in reference to prognosis, when we first see the case,

we should not persist in our efforts at the risk of augmenting the inflammation or the patient's sufferings. The œdema of the eyelids declines in the progress of the affection, and then one or both of them may become everted, the convex edge of the tarsal cartilage being pushed forwards by the swollen conjunctiva. The inflamed membrane exhales at first a thin whitish mucus in small quantity; as the inflammation proceeds to its full development, the discharge becomes thicker, yellow, and abundant; the yellow tint and the quantity of the exhalation being in proportion to the violence of the inflammation. When the latter is at its height, the discharge closely resembles in its appearance, and in the stain communicated to linen, that which proceeds from the urethra in venereal gonorrhœa. Although the pain is generally most severe both in the eye and in the head, as in other instances where the dense and unyielding texture of the cornea is the seat of inflammation, and although patients often complain of burning pain, of tension, as if the eye would burst, of deep-seated and intense agony, with extension of these distressing and almost intolerable sensations to the brow, forehead, and head generally, there are some instances in which little or no pain is experienced. The symptoms of acute gonorrhœal ophthalmia are not equally violent through the whole course of the affection: it begins with swelling and increased redness of the conjunctiva, and some pain in the organ: then the puriform discharge takes place, with increased uneasiness: and, lastly, the inflammation extends to the cornea, with great aggravation of suffering. Thus the course of the affection may be divided into three stages, of which the limits cannot be marked very accurately. In the first there is vascular distension and swelling of the membrane, with swelling of the lids; the commencement of the second is marked by the occurrence of the puriform discharge, and that of the third by extension of the inflammation to the cornea. The duration of each of these varies in different instances according to the constitution and state of health of the individual, and perhaps still more according to the nature of the treatment adopted. This variety, however, is observed less in the first and second than in the third stage; the two former, and more particularly the first, usually passing off very rapidly."

In gonorrhœal ophthalmia, the immediate destructive effects of the inflammation, sloughing, abscess, and ulceration of the cornea, are more to be apprehended than in common purulent ophthalmia as it now occurs. The appearance of the cornea when about to slough or suppurate has been already described; the process, as it occurs in the present form of inflammation, is described as follows by Mr. Lawrence. "The cornea becomes dull and hazy before it sloughs, or indeed before undergoing any of the changes above enumerated. Its transparency and polish are completely destroyed where it has sloughed; and it is converted into a dirty yellowish or brownish opaque surface, which is immediately recognised as deprived of life. At first it looks like a portion of wetted leather; it is soon separated from the living parts, when it has a loose, soft, and ragged appearance. As the lens and capsule which are exposed by this separation are transparent, the patient sometimes recovers for a short period tolerably good vision. After the slough is detached, the chambers of the aqueous humour may be exposed by ulceration; the humour will then escape, the empty coats will collapse, and the globe remains permanently shrunk in the socket. More commonly, although the whole cornea seems to slough, the entire thickness does not separate, and the anterior chamber is not exposed." The slough of the cornea, when it does cast off, leaves an ulcerated surface proportioned to the size of the slough, with or without an opening into the anterior chamber. If the slough or ulcer does not extend through the thickness of the cornea, the consequence is simple opacity or staphyloma; if it does not penetrate into the chamber of aqueous humour, the iris passes through the opening, and the patient suffers from closed, contracted, or irregular pupil in addition to the opacity. But it is not by slough alone that these evils are produced: suppuration or abscess is liable to occur. It is thus described by Mr. Lawrence: "Suppuration of the cornea may be general or partial: it is usually the former. The cornea first becomes white, and then assumes a yellow colour. The effused substance is not a fluid, nor is it collected into a cavity: it is a thick viscid matter deposited in the texture of the cornea. Ulceration takes place, and exposes an opaque yellow substance, which looks like ordinary matter, but it cannot be wiped off." The abscess of the cornea thus opened by progressive suppuration goes on to ulceration, and may extend to the anterior chamber as in the sloughing process, and with similar consequences. The successive changes in the ulcer are thus described. "If the ulcer should be spreading, the inflammation remaining unchecked, its surface is whitish and ragged or flocculent, or of a dirty yellowish cast with surrounding haziness. When the inflammation subsides, it becomes transparent. The commencement of the restorative process is marked by the surface of the excavation assuming a light greyish tint with a jelly-like appearance. A soft semi-opaque substance fills up the breach, when the surface becomes smooth, and the regular figure of the cornea is restored."

The *prognosis* in gonorrhœal ophthalmia must obviously be most cautious, and the patient should at once be informed respecting the nature of his disease, and the dangers to be apprehended. The first and most destructive consequence to be feared is the sloughing of the cornea; a change of appearance in the eye indicative of such disorganization is therefore to be watched for with great attention. This change is a haziness, or loss of the natural transparency of the cornea, proceeding rapidly to complete dirty white opacity, subsequently becoming total or partial slough, with edges defined by the suppurative process, which separates dead from living parts. The appearance of abscess is later than that of slough, but, when observed even in the slightest degree, should be viewed with nearly equal apprehension, as it is impossible to determine the extent to which it may enlarge either in depth or breadth, while in the state of abscess or that of ulcer. After the more acute period has passed over without either slough or abscess, the appearance of even a small

speck of ulceration is also calculated to excite alarm, as it is often most difficult to arrest the progress of this process before it produces irreparable injury of the organ. After the patient is relieved from apprehension respecting these destructive consequences, he should still be taught to understand that his recovery is to be slow and even doubtful; the change of organization in the conjunctiva, and its conversion into the peculiar granulated condition, with permanent red vascularity of the conjunctiva of the eye-ball and opaque cornea, may still prevent recovery; or even without such disorganization, the cure may be greatly retarded by the influence of scrofulous constitution or the local disease. Mr. Lawrence says, "of the fourteen cases which I have related, loss of vision took place in nine from sloughing, suppuration, or opacity of the cornea. In two of these one eye was lost, and the other recovered. Sight was restored in the other five, with partial opacity of the cornea, and anterior adhesion of the iris in three of the number. So short a period intervenes between the commencement and the full development of the complaint, that in many instances irreparable mischief is done to the eye before our assistance is required. If we see the complaint in the first or second stage, we may expect to arrest its progress by active treatment; but success does not invariably attend our efforts. Our prognosis will principally turn on the state of the cornea; if that should possess its natural clearness, the eye may be saved. If it should become hazy and dull, and more particularly if it should have assumed a white nebulous appearance, consequences more or less serious will inevitably ensue. Great swelling of the conjunctiva, more particularly great chemosis, profuse discharge of a yellow colour, and bright redness of the swollen upper eye-lid, are unfavourable circumstances, as indicating a high degree of inflammation. When both eyes are attacked in succession, the disease is less severe in the second, which, therefore, is usually saved. Sometimes, however, the inflammation is equally violent in both."

In investigating the **Causes** of gonorrhœal ophthalmia, inquiries highly interesting, even in a general point of view, are suggested. It has been supposed that the specific form of gonorrhœal inflammation existing in the urethra is transferred to the conjunctiva by that obscure and inexplicable transition which is denominated metastasis, respecting which we know little more than the fact of its occurrence. This metastasis never has, and perhaps never can be proved to occur, because there can be little doubt that the contact of gonorrhœal matter with the conjunctiva produces the disease of the eye, and it is impossible to prove positively that such contact does not take place in all cases of gonorrhœal ophthalmia. Every individual affected with gonorrhœa must have the fingers contaminated by the discharge, notwithstanding the most scrupulous cleanliness and care; and the application of the fingers to the eyes for the removal of any irritation there is so habitual, that it becomes an involuntary act, which nothing but continued watchfulness could prevent, and which may occur even during sleep when the patient is unconscious of it. It is true that a person may be so attentive to the prevention of this occurrence, by the utmost precaution and cleanliness, as to render it highly improbable that a particle of matter has been applied to the eye; but the attendant can only say in such case, this is most probably metastasis of gonorrhœa to the eye, but cannot safely assert positively that it is so. While it appears thus impossible to say with certainty that metastasis has occurred, it is equally impossible to prove that it has not; and many facts and arguments may be adduced in favour of the conclusion that this is the mode in which the disease originates.

The disease of gonorrhœa affords other apparent examples of metastasis. The violent inflammation of the testicle produced by suppression of the discharge from the urethra is surely rather of this character than an extension of the mucous inflammation along the lengthened and tortuous tube of the vas deferens. Irritable bladder, produced by the same cause, is also most probably independent of a continuous extension of the specific inflammation along the whole length of the urethra to the lining membrane of that organ; and even sympathetic buboe generally presents characters so different from that which arises from the extension of irritation along the absorbents to the lymphatic glands from simple injury, that it is not unreasonable to attribute it to metastasis. These metastases are of comparatively rare occurrence; so is gonorrhœal ophthalmia, notwithstanding the probability of the frequent application of the matter to the conjunctiva or its vicinity. The occurrence of the disease in one eye without extending to the other, notwithstanding the profuse discharge so likely to come in contact with the unaffected organ, makes it highly probable that the disease depends on a cause different from mere contact of infectious matter. Whatever doubt may be entertained respecting the occurrence of metastasis, evidence sufficient to prove that the disease can be produced by the contact of gonorrhœal matter, both in the individual labouring under the disease of the urethra as well as others, is on record. Mr. Lawrence, Mr. Wardrop, M. Delpech, Mr. Bacot, and others, state instances in which there could be no doubt of the fact. The writer of this has had this assigned as the cause of the disease by a young man, who without any leading question or knowledge of the usual production of inflammation of the eye by such a cause, stated circumstantially the fact of gonorrhœal matter having been projected into his eye while retracting the prepuce, which confined a quantity of the discharge. Dr. Vetch details a solitary case in which the experiment was made to determine this matter by an hospital assistant; and where gonorrhœal matter was applied to the conjunctiva with impunity. It does not, however, appear that Dr. Vetch himself conducted the experiment; and it is obvious that much confidence could not be reposed in the accuracy of an individual so imprudent and thoughtless as to incur such a risk. While it may be admitted that the contact of gonorrhœal matter to the eye produces conjunctival inflammation, it is by no means proved that it uniformly has this effect. Some individuals may possess this dangerous susceptibility, and others not; and even the same individual may at one time suffer

from the contamination, and at another time not. Should it be established by observation that this is the fact, it would be an important illustration of the general question of contagion, proving that a morbid poison directly applied to a circumscribed spot produces effects at one time and on one person, which are not observed on other persons or on different occasions. Upon a candid consideration of this subject, it must be admitted that it is the duty of the practitioner to warn patients labouring under gonorrhœa, of the danger they incur by negligence or inattention, with respect to the precaution necessary to prevent the communication of the disease to the eye.

With respect to the **Treatment** of gonorrhœal inflammation, it is scarcely necessary to observe that the plans suggested for the relief of common severe purulent ophthalmia should be carried into effect with the utmost vigour. Mr. Lawrence observes, in alluding to the advantage of depletion: "The only chance of arresting this violent disorder, and preserving the eye from its destructive effects, is afforded by the boldest antiphlogistic treatment, particularly by the freest abstraction of blood, locally and generally. We must bleed largely from the arm, and take blood by cupping on the temples, or by numerous leeches applied round the part; and these measures must be repeated at short intervals, until the vascular congestion is relieved and the attendant pain removed. The other parts of the antiphlogistic treatment must be combined with the free abstraction of blood; but our great reliance must be placed on the latter. I think that as much blood should be taken from the arm as will flow from the vein; and that the evacuation should be repeated as soon as the state of the circulation will allow us to get more." Mr. Bacot and Mr. Wardrop concur in the opinion respecting the value of depletion. Mr. Guthrie, on the contrary, places little confidence in its effects, and relies upon the application of the ointment of nitrate of silver, as administered in severe purulent ophthalmia. He even attributes the loss of the organ in this disease to inordinate bleeding: he says—"The history of all cases of this disease, hitherto recorded, is but a melancholy story of lost eyes. The reason of this loss is, that they all pursued a similar plan of treatment; viz., they invariably bled the patient to a very large quantity; one hundred, one hundred and fifty, and even two hundred ounces, are stated as having been drawn, until the patients were blanched as white as a sheet, or a piece of white wax. This was accompanied by a due proportion of purgatives, emetics, and emollient fomentations, with mild, astringent lotions and leeches, until in time the eye or eyes were lost, and the case was brought to a conclusion. As long as I followed this course I fared no better than those around me, but successive failures led me at last, almost in despair, to adopt a very opposite method, which has proved, at least in my hands, much more effective, and will, I trust, in those of others, remove the opprobrium which has been attached to this part of surgery." He then proceeds to describe the mode of application of the ointment of nitrate of silver formerly alluded to, and observes, "I do not mean to say that one application will alter the action, and restore the parts to a healthy state; it must be re-applied; neither is the ointment to do every thing; it may, and must, of course, occasionally fail." These conflicting opinions may perhaps be reconciled. Bleeding is undoubtedly a resource of the utmost value and importance in the general treatment of gonorrhœal ophthalmia, and the ointment recommended by Mr. Guthrie is an application also of value. The practitioner will therefore avail himself of both, as circumstances require. Even Mr. Guthrie, relying as he does on the stimulating astringent, recommends moderate bleeding in conjunction with it; and in the application of the nitrate of silver ointment in common, severe purulent ophthalmia, enjoins venesection as an accompaniment. It is certain that a coarse, brawny, plethoric, carnivorous man must be freely bled to save his eyes from destruction in this complaint; while a similar practice adopted towards a pallid, languid, feeble individual, would prove at least inefficient, if not injurious. The experienced practitioner will, therefore, proportion his efforts to the resistance, and adjust his treatment to each case according to its symptoms.

It is unnecessary to repeat the observations respecting the treatment of severe purulent ophthalmia, except to remind the reader that they are equally applicable to the form of disease under consideration. It is obvious, however, from the specific character of the gonorrhœal inflammation, that mercury, from its influence on disease at least allied to this, deserves more consideration as a remedy in this than the common form. It is, however, notorious, that whatever necessity the practitioner may see for the administration of mercury to correct the mischief to be apprehended from the specific disease, he cannot rely upon it to cut short the inflammation. Mr. Lawrence says—"I have seen both the ordinary purulent and gonorrhœal opthalmia proceeding apparently unchecked under the full mercurial action." Some practitioners, however, place reliance on this remedy, and some, assuming as a matter of course that it ought to cure the disease, administer it in every instance. The writer of this, considering that mercury is a poison which should not be introduced into the system without absolute necessity, and positive evidence of its beneficial effect in correcting morbid action, feels no inclination to recommend its administration in gonorrhœal ophthalmia.

On the supposition that this disease depends on metastasis, and relying on the unproved assumption that it is accompanied by a suppression of the discharge from the urethra, it has been proposed to reproduce that discharge by irritating or stimulating that passage. This resource has been recommended by the German writers in particular, who have perhaps weakened the confidence reposed in their opinions by practical men in this country, by their proneness to mould practice on preconceived theories and unauthenticated facts, as well as by their reliance on antiquated doctrines, authorities, and nostrums. There is no evidence before the profession to prove, either that the discharge from the urethra ceases with the appearance of the ophthalmia, or that, if it does, its restoration removes the affection of the eye. Mr. Lawrence observes, after quoting the authority of Richter, Scarpa, and Beer, as to the expediency of reproducing the urethral discharge, "In spite

of the confidence which one is inclined to repose in the practical knowledge and judgment of those whose advice has just been quoted, I cannot help thinking that the measures in question have been recommended rather on theoretical grounds than from experience. At least these writers do not mention any results of their own practice; nor have I met with any cases in which the employment of such means is mentioned. In none of the instances which have come under my own observation has the gonorrhœal discharge been suppressed, so that the reason for this kind of practice has not existed. Again, when the violence and rapidity of the disease are considered, in contrast with the slowness and uncertain operation of this treatment, we cannot doubt that irreparable injury would be done to the organ during the time lost in such attempts.

Purulent Ophthalmia of Infants.—This is a most formidable disease; indeed it is probable that the loss of vision from this cause is four times greater than that from all the cases of common purulent and gonorrhœal ophthalmia put together. It is particularly necessary that the young practitioner, especially the accoucheur, should be aware of this, because some writers describe the complaint as trivial, and its treatment as attended with little difficulty. This opinion has probably arisen from the circumstance of the frequent occurrence of a very mild form of conjunctival inflammation in new-born infants, unattended by any destructive consequences, and generally disappearing without medical aid. The disease now under consideration presents all the characters of the severest purulent ophthalmia. The vascularity is enormous, but in consequence of the organization of the parts, and the yielding of the texture of the lids at this early period of life, there is less of chemosis than general tumefaction of the coverings of the eye. The pain, if a judgment may be formed from the extent of the inflammation and the sufferings of the infant, is very great. The purulent discharge is as profuse as in the worst forms of common severe purulent or gonorrhœal ophthalmia. The consequences are equally formidable; and destruction or injury of the organ by slough, abscess, and ulcer of the cornea, prolapse of the iris, staphyloma, or escape of the contents of the eye-ball, equally to be dreaded. There is one consequence, however, most destructive in purulent ophthalmia in adults, not encountered here; this is the permanent alteration in the structure of the conjunctiva, proceeding to red vascularity of the transparent part of the membrane, and granular lids. The escape from this description of disorganization, of such frequent occurrence at more advanced periods of life, arises probably from the high degree of vital energy and active operation of the functions of growth and nutrition existing at this period.

The disease generally commences within the first three days after birth. The eye first appears moister than natural; redness of the lids ensues; a small quantity of purulent matter collects in the inner canthus; the white of the eye is slightly bloodshot; and the child shuns the light and becomes restless and peevish. All these symptoms are speedily aggravated; the vascularity becomes intense, causing tumefaction of the lids externally, and a pulpy villous condition of them internally; but the redness of the conjunctiva over the ball seldom extends to chemosis. The purulent discharge becomes profuse, completely glueing up the lids during sleep, and often accumulating beneath them in such quantity as materially to increase the distress; and when the eyes are drawn asunder, it so completely fills the space between the lids as to prevent the observer from obtaining a view of the cornea: it accumulates with such rapidity, that if completely washed away with a syringe, it is replaced by a fresh secretion in ten minutes or a quarter of an hour. The discharge is usually of the colour of common purulent matter, but is sometimes tinged with blood; or if the child be jaundiced, has a greenish tint. When the infant cries, the tumefaction of the lids increases enormously, and sometimes they become everted, exposing the red vascular surface to the air. This is the period at which the sloughing process takes place; it is well described by Mr. Saunders in his Treatise on Diseases of the Eye, published after his death by Dr. Farre. His words are quoted here because they are obviously those of an accurate observer enjoying ample opportunity of acquiring correct information; and because they are the observations of the man who first applied the sound principles of Hunterian or English surgery to the investigation of ophthalmic diseases. He says, "As the disease advances, the cornea becomes more or less cloudy, and by the extent of this cloudiness the degree of approaching slough is marked: for the whole of the cornea, if the whole become cloudy, will ultimately slough, and the form of the eye be totally destroyed. I do not mean to say that in every instance in which opacity of the cornea is apparent, the cornea is about to pass into a sloughy state; on the contrary, opacity is often the mark of a healthy action, commencing around the breach of the cornea, for the purpose of restoring the part, and ought to be hailed as a happy omen. I am now speaking of a peculiar duskiness of the cornea, which begins during the progressive state of the inflammation, which is antecedent to any loss of substance, but is indeed a sure sign that such loss is about to take place. When this duskiness comes on, supposing only a portion of the cornea about to slough, the extent of it in the space of twenty-four hours becomes definite; in the same space of time it becomes elevated and apparently lessened in extent; a groove or fissure forms between it and the rest of the cornea, portions of it are carried off by the discharge and tears, or sometimes it separates altogether in one mass. I have several times washed out with a syringe these little sloughs entire. But although I am as certain of the fact as the most frequent observation can make me, I am equally sure that most commonly when this disease destroys vision, the destruction is accomplished in a more gradual manner, not by a slough of very considerable extent and through the whole depth of the cornea at once, but by a succession of sloughs. In other words, the ulcer left by the casting off of the dead piece of cornea becomes in turn sloughy, and extends itself by a succession of sloughy surfaces, until the last lamina of the cornea sloughs, or being protruded by the pressure from within, ulcerates, and the

aqueous humour escaping, the iris passes through the breach of the cornea. Already the whole surface of the eye has been in an ill-conditioned inflammation; the ulcer, or rather the surface of the cornea, around the protruding iris is indisposed to heal, so that more and more of the iris protrudes; this in turn ulcerates, and the crystalline and vitreous humours all issue at the orifice. That the inflammation itself immediately destroys the parts by sloughing or ulceration is a truth of which I am perfectly convinced."

Mr. Mackenzie, in his treatise on Diseases of the Eye, observes with respect to these opinions of Mr. Saunders, "It is scarcely necessary to spend time in refuting Mr. Saunders's notion of its being an erysipelatous inflammation. His opinion regarding the mode in which the cornea is destroyed in this disease appears of more importance and equally incorrect. He maintains that it is by sloughing, not by suppuration and ulceration, that the destruction of the cornea is effected. The opportunities which I have had of watching the progress of the affection of the cornea have convinced me of the contrary. Onyx or infiltration of pus between the lamellæ of the cornea is the uniform harbinger of destruction; the lamellæ exterior to the pus give way by ulceration; the ulcer spreads and deepens till the cornea is penetrated, and often almost altogether destroyed. Any thing like mortification or sloughing I have never seen. The coming away of the purulent infiltration exposed by ulceration must have given rise to Mr. Saunders's notion of successive slough."

Whether the inflammation be erysipelatous or not may be ascertained when pathologists have determined what the term erysipelatous so applied means. If the cornea ever sloughs in severe inflammation of the conjunctiva, it may be admitted that it does so in this, especially if men of experience agree that such is the case. Mr. Mackenzie is undoubtedly right in stating that the eye is lost in this disease frequently by abscess; and the fact perhaps is, that the two processes are often combined; the dirty ragged ulcer consisting of open abscess with sloughy surface, and being very much of the character of anthrax. Whatever opinion may be entertained respecting the precise nature of the destructive process, the practitioner should never lose sight of the danger to be apprehended from it. It commences during the active period of the inflammation, but continues after it is mitigated, and, if not arrested, terminates in destruction of the organ.

The investigation of the *causes* of purulent ophthalmia in infants is not attended with much difficulty. It may readily be admitted that the exposure of the infant to cold, immediately after its expulsion from the uterus, will probably produce inflammation of this description; and to this cause may reasonably be attributed the frequency of a milder form of conjunctival inflammation at this time of life, which does not assume the violent character of the other. The resemblance between this severe form and Egyptian or gonorrhœal ophthalmia justifies the suspicion that it is of equally distinct specific character, and to be traced to a cause equally peculiar. This cause may be the application of the matter of leucorrhœa or gonorrhœa to the eyes during labour. The extent to which this cause operates, however, has not been fully ascertained, and the proof of its influence exists more upon conjecture and reasonable inference than actual practical evidence. The practitioner knows, from daily observation, that women labouring under leucorrhœa and even gonorrhœa produce children unaffected by this disease; but he should be equally aware that in the majority of cases of purulent ophthalmia the mother labours under one of them. The accoucheur should, therefore, make himself acquainted with the truth as to this matter, and direct that a sponge and basin of warm water be ready to cleanse the face and eyes of the infant immediately after birth, and if possible before the lids are opened. If it be known that the mother labours under gonorrhœa, the practitioner should watch the approach of inflammatory action in the first three or four days after birth, and immediately resort to those vigorous measures already enumerated to arrest its progress. These precautions may possibly be superfluous, and disregarded or neglected in the common routine of extensive practice; but if one child be preserved from blindness by them in the course of a practitioner's life, it is sufficient return for the trouble.

The **Prognosis** in this purulent ophthalmia is a matter of considerable importance to the professional welfare of the practitioner. In consequence of the frequent occurrence of the mild form of the disease, those who have not experienced the destructive effects of the other are liable to overlook its approach, and allow the process of slough or abscess to proceed without interruption. As soon as the disease has appeared in the virulent form above described, the parents should at once be informed that it is liable to terminate in serious injury or destruction of the organ. Persons of the lower order, unprovided with medical assistance at their confinement, generally allow the disease to proceed without interruption during the period at which any hope could be entertained of averting the destructive consequences. They seldom seek relief until a week or fortnight after the first attack, and then in consequence of not finding the purulent discharge and tumefaction subsiding, as they were led to expect. When an infant, at this period of the complaint, is presented to the practitioner, he should at once satisfy himself whether the cornea be safe from slough, abscess, or ulceration, or, as this is attended with some trouble, if leisure does not permit him to do so, he should inform the parent in plain and intelligible language, that there is danger to be apprehended, and that the child may have its vision impaired or destroyed by opacities of the cornea, which cannot at the moment be perfectly distinguished. If he dismisses the patient without this precaution, or if he makes any application to the eye without explicitly announcing the extent of the injury, the reproach of having blinded the child will be fastened on him by those who, from culpable negligence, ignorant confidence in their own opinions, or sordid love of money, had caused so lamentable a misfortune. If, upon examination in this after period of the disease, the cornea be found perfectly clear and free from ulcer of any kind, the practitioner may entertain sanguine hopes of perfect recovery, but he should not even then give ex

pression to these hopes, as relapse may occur, or some accidental circumstance interfere with the cure. If slough, abscess, or ulcer have not taken place in the first week or ten days, there is every reason, from experience, to expect that no further bad consequence is to be apprehended than the troublesome and distressing vascularity with profuse purulent discharge, which often, especially if not checked by astringents, continues for six weeks or more. It has already been observed that the high degree of vascularity which accompanies this disease does not degenerate into permanent disorganization of the conjunctiva with opaque cornea and granular eyelids; at least this is the result of the experience of the writer of this article: further observation may, however, enable others to correct or modify this assertion.

To the **Treatment** of purulent ophthalmia in infants, the principles laid down respecting the other severe forms of conjunctival inflammation are applicable. As soon as the existence of the disease is fully ascertained, a leech should be applied over the cheek-bone at the edge of the orbit, and blood allowed to flow until the effect of the bleeding becomes obvious by the paleness or sickness of the infant. One or two leeches, at most, on each side, are sufficient for this purpose; and as all the effects of general bleeding are produced by the application of leeches at the earlier periods of life, and as the flow of blood does not usually cease spontaneously in infants, on account of the great vascularity of the skin, the medical attendant should not lose sight of his patient until he has secured such arrangements as will prevent the possibility of the child's life being endangered by hemorrhage. It is on this account that the leeches should be applied on the cheek-bone at the edge of the orbit, where, from the resistance of the bone beneath, circumscribed pressure may be made without delay. The bowels should be emptied completely; and for this purpose a grain of calomel, with castor oil or any other purgative to which the practitioner may be partial, may deserve a preference. If it be admitted that the administration of calomel influences the biliary secretion, its use is particularly indicated at this period of life, when the liver performs an office in the animal economy of still greater importance than it does at more advanced periods. If the child continue to suck voraciously, it may be desirable to rid the stomach occasionally of the accumulated milk by the administration of a small quantity of ipecacuanha or other emetic medicine. As soon as the purulent discharge becomes profuse, care must be taken to prevent it from accumulating with the tears beneath the lids, and producing by mechanical distension an increase of the irritation and distress. This accumulation is frequently produced by the eyes becoming sealed up by the evaporation of the fluid part of the discharge which has collected on the outside of the lids. To prevent it, the eyes should be perpetually sponged gently with lukewarm water, and by laying a scrap of old linen squeezed out of warm water over the eyes as the infant lies on its back in bed. The edges of the lids may be touched with a little cream when the child settles for a longer sleep, and when it awakes the lids should be gently drawn open, and the accumulated matter forced out by light pressure and motion of them. Repeated syringing of the eye is unnecessary, and is often injurious by adding to the irritation: the purulent discharge causes no mischief but by its bulk producing distension in the way above stated, and is probably the best, being the most natural, protection of the surface against the contact of the tears. When the practitioner makes his visit, it is, however, necessary to wash away the discharge completely, in order to obtain a perfect view of the cornea; this may be done with a syringe, for which purpose a neat silver one with a fine orifice should be used; but as this may not be at hand, and as many may not wish to run the risk of spattering the discharge into their own eyes, a more simple and equally efficacious method may be adopted: the infant's head being laid on the knees of the operator while the body is supported by the nurse, the eyes should be well sponged externally, and the lids drawn open and closed repeatedly, so as to extricate the discharge, which should again be removed with the sponge. After the child ceases to cry, a few drops of warm water should be allowed to flow into the eye between the lids out of a large camel-hair pencil, and the lids opened and pressed as before, after which the child should be, if possible, set asleep, and then the eyes being suddenly drawn open, a full view of the cornea may be obtained.

Local applications may be resorted to with two objects—the alteration of the nature of the inflammatory action altogether, or the diminution and removal of the purulent discharge. For the former object, the nitrate of silver is recommended, and it cannot be denied that it may effect it; but it must at the same time be confessed that the practice has not yet been fully submitted to the test of experience. The question for consideration is, whether a practitioner, as soon as he has ascertained beyond doubt the existence of this severe form of inflammation, can with safety, and a fair prospect of advantage, introduce a solution of nitrate of silver of ten grains to the ounce, or an ointment of ten grains to the drachm, between the lids. That this and other astringents may be used with success to put a stop to the purulent discharge, after the first symptoms of inflammatory action have been subdued, cannot be doubted. With this view, a five-grain solution of nitrate of silver, or saturated solutions of acetate of lead or alum, may be resorted to: the acetate of lead cannot, however, be employed if slough or ulcer be present. A large drop of saturated solution of alum may be put into the eye once or twice in the twenty-four hours, and the nurse may be allowed a weaker solution of four or five grains to the ounce to use occasionally. Mr. Mackenzie recommends a solution of one grain of corrosive sublimate, in an ounce of water, as a wash to be freely used.

If slough or abscess has taken place, it does not appear that any other than the plan of treatment above stated can be adopted, or that any local application can be made likely to suspend the progress of either one or the other. Mr. Saunders, reasoning on the fact that bark and other tonics are employed with advantage in gangrene, and that the slough of the cornea is of this character, directed the administration of extract of cinchona in such cases. It does not, however, appear that

the cases are analogous, or that the remedy does actually prove of advantage. The slough, or abscess, is, in the present case, a consequence of intense inflammatory action, not followed by any diminution of vital action, locally or generally, consequently not requiring remedies intended to invigorate the constitution, or accelerate the functions of circulation and nutrition. The suggestion of Mr. Saunders does not appear to have been much acted upon in general practice. After the slough of the cornea has been cast off, or the abscess completely converted into healthy ulcer, or if the iris be prolapsed and has assumed a red, granulating appearance, the greatest service the practitioner can afford his patient is, to prevent any injudicious interference with the natural processes of reparation which are in progress.

Scrofulous Ophthalmia.—The consideration of what is called scrofulous ophthalmia need not detain the reader long, if it be admitted that there is no inflammatory affection of the eye which displays at its onset such characters as entitle it to be considered specifically distinct. In fact, there does not appear to be any such disease, strictly speaking, and what is commonly called scrofulous ophthalmia is nothing more than the modification of any of the preceding forms of conjunctival inflammation by that condition of constitution which we denominate scrofulous. There can be no doubt that every one of the preceding forms of inflammation, and indeed every form of inflammation of the eye, is liable to assume the scrofulous character, except the purulent ophthalmia of children, which is not so modified in consequence of the organization of the system at that time of life.

The symptoms considered characteristic of scrofulous ophthalmia do not present themselves for some time after the first attack, and when the inflammatory period has subsided, and the chronic stage fairly set in: then it is that the progress to recovery is interrupted; the conjunctiva does not return to its natural condition; light becomes painful; the tears flow copiously; the purulent discharge is diminished; and the continued vascularity causes opacity of, and extension of red vessels to, the conjunctiva of the cornea; [and, according to Dr. Taylor, (Tweedie's *Library of Medicine*, 2d Amer. edit., ii. 145, Philad. 1842,) towards evening, especially after sunset, considerable remission of the symptoms takes place, which had been aggravated through the day: a phenomenon which, according to him, is not observed in any of the other forms of ophthalmia.] To correct this destructive condition, the obvious resource is in those means universally admitted to exercise a salutary influence on the functions of circulation, secretion and nutrition. They may be summed up in a few words: respiration of a pure atmosphere, warm clothing, generous diet, bark and other tonics, warm, salt-water baths, and bathing in the open sea. It is in this condition of the eye that the chronic vascularity may be most effectually removed by the daily application of a saturated solution of acetate of lead, or the aqua lythargyri acetati dropped between the lids night and morning. It is also in this modification of the chronic vascularity, with great intolerance of light and profuse scalding lachrymation, that the vinous tincture of opium affords most relief. Blisterings, which may be resorted to in any of the preceding forms of inflammation, appear particularly serviceable here, and should be repeated as often as they heal, either on the temples, at some distance from the eye, or behind the ears. Free exposure of the eyes and face to the air and light is an important part of the treatment, although a part generally neglected or actually interdicted. There can be little doubt that the miserable condition in which neglected or mismanaged children are frequently found, with the face scalded with tears, the head averted, and crying or sneezing on exposure to light, is produced by confinement to a dark, close room, and covering the eye with a green shade.

Arthur Jacob.

[It has been recommended recently by Dr. Hocker, and by Mr. Wormald, (*Lond. Lancet*, Nov. 19, 1842, p. 285,) to apply the solid nitrate of silver to the eyelids. A clean stick of the nitrate, having from one to two inches exposed, is selected; the patient's eyelids are closed, and put slightly on the stretch, by applying the thumb of the left hand to the eyebrow, and gently raising the skin; the nitrate, moistened, is then to be passed over the whole surface of the skin of the upper, and, subsequently, of the lower eyelid, two or three times, smoothly, and without much pressure, bringing not the point but the sides of the stick in contact with the skin. The object is only to blacken, not to occasion any severer effects. In this manner, it is affirmed, the sensibility of the fifth pair of nerves is diminished, and the lachrymation and photophobia are relieved. Similarly good effects are stated by Dr. Furnival, (*London Lancet*, Dec. 10, 1842, p. 405,) to result from painting the palpebræ of the affected eye with the tincture of iodine, pure or diluted.

Variolous Inflammation of the Conjunctiva.—Variolous pustules may form on the conjunctiva, as upon any portion of the cutaneous surface. In the opinion of some, however, the eye suffers in small-pox from common inflammation merely, although of a very severe form. The pustule appears, at first, as a small white point, which gradually becomes elevated and yellow; and in spite of every care, if the pustule be over the cornea, vision may either be wholly lost, or impaired by opacity or ulceration. Where suppuration or sloughing of the cornea occurs, it may be followed by the various lesions of the eye-ball, more than once referred to. At times, *secondary variolous ophthalmia* occurs at the time when the pustules are disappearing from other parts of the body. It is milder than the variolous conjunctivitis just described, but may be attended with mischief. It seldom, however, terminates in destruction of the cornea. Opacities are much more likely to be left. The period of the attack varies from two to six weeks, after the apparent termination of the primary complaint.

The **Treatment** is the same as in all severe cases of ophthalmitis. General bleeding may be required, or, if not, it may be advisable to take blood locally. When pustules form, they should be opened early, and be cauterized with the solid nitrate of silver. The same application is advisable when they burst.

The secondary form of variolous inflammation

may require topical bleeding and cathartics, in the first instance; but afterwards an opposite course is generally advisable, and the sulphate of quinia alone, or associated with other tonics, may be indicated. Vinum opii and a solution of nitrate of silver, or the solid nitrate of silver, are amongst the best topical applications.

Inflammation may also attack other parts of the eye.

Inflammation of the Sclerotica.—Inflammation of the sclerotic coat of the eye does not often exist alone; being either accompanied, from the first, or speedily followed, by conjunctivitis. The iris and cornea suffer to a certain extent, although, unless from neglect or mismanagement, serious alteration of structure in either is not common.

Diagnosis.—There is a general bright redness of the globe of the eye, especially around the cornea, towards the margin of which the radiated vessels of the sclerotica are seen advancing, and, along with those derived from the conjunctiva, passing over the cornea to the extent of about half a line, forming a fine vascular wreath, which encircles the cornea wholly or in part, and in which all the vessels are observed to terminate with sharp points, and at an equal height: none pass beyond it, the rest of the cornea remaining free. This arrangement and mode of termination of the vessels has been considered, by Jüngken, characteristic of *rheumatic sclerotitis.*

In the progress of the inflammation, the iris becomes implicated, as indicated by contraction of the pupil, easily seen by comparing the sound with the affected eye: the iris, also, is less active than usual. The capsule of the aqueous humour is affected, giving occasion to haziness of the cornea. The pain of the eye-ball is severe, and of a stinging or darting character, extending to the orbit, forehead, cheek, and occasionally along the branches of the fifth pair of nerves to the face. The pain is usually increased by warmth, and is especially severe from sunset to sunrise.

There is always, along with those symptoms, a considerable secretion from the eye; but, instead of its being mucous, as in inflammation of the conjunctiva, it consists of the secretion from the lachrymal gland. Photophobia or intolerance of light is always present, but it varies in degree in different cases. The same may be said of the constitutional irritation: fever almost always exists, but, at times, to a much greater degree than at others.

The inflammation is often restricted to one eye, and frequently alternates with rheumatic affections in other parts of the body. It also leaves a strong predisposition to recurrence on the application of slight causes.

The disease is not often seen in children and old persons.

Treatment.—The treatment of sclerotitis should be active, especially if the patient be plethoric, and there be much constitutional irritation. Blood may have to be taken from the general system, and the operation may be repeated again and again, unless the symptoms are relieved. Cupping and leeches and blisters may also be used, as in the forms of ophthalmia already considered. Cathartics may be prescribed as revellents, and calomel and opium be administered, so as to touch the mouth gently.

In regard to local applications, they should generally be used warm. They may consist simply of warm water, or warm milk and water; or warm decoction of poppy-heads. Warm opiate frictions have been advised to the temple and forehead, with the view of averting, or relieving, the nocturnal paroxysm of pain. Warm laudanum, or warm wine of opium, may be used for this purpose, or a liniment of soap with opium. It has been advised, that these opiate frictions should be used especially about an hour previous to the expected attack.

Applications to the eye, in the form of collyria, have not been found of much service, and those that are excitant are injurious during the early stages. When, however, the acute symptoms have passed away, and *à fortiori* when they become chronic, vinum opii—pure, or diluted—dropped between the eyelids, is often beneficial. In such cases, too, especially when they are associated with evidences of a strumous diathesis, tonics, as sulphate of quinia, or arsenic, may be successfully administered.

Throughout the whole course of the disease, the iris should be kept under the influence of belladonna.

At times, the catarrhal and the rheumatic varieties of ophthalmia are combined, constituting *catarrho-rheumatic ophthalmia;* the presence of which may be diagnosticated, from a knowledge of the functional phenomena exhibited by the two varieties respectively. The cornea is very liable to suffer in this form of ophthalmia from ulceration, abscess, or interstitial deposition; or the inflammation may extend to the iris, so as to terminate in the effusion of lymph, and in obliteration of the pupil.

More activity of treatment is required than in sclerotitis; and in addition to the remedies advised under the latter affection, the employment of the local agents recommended in the catarrhal variety is demanded.

Inflammation of the Cornea.—Inflammation of the cornea is apt to form a part, by extension, of the different forms of inflammation of the eye, that have already received attention. Ceratitis proper, however, commences in the cornea, whence it may spread so as to attain other tissues. In many cases, it is simple, as where it has been caused by any extraneous substance, as a particle of metal imbedded in the substance of the cornea; or, what is considered by some to be more common, it originates frequently in the scrofulous diathesis, and has been thought to merit the distinctive appellation of *strumous corneitis.*

Diagnosis.—The disease generally commences slowly, and insidiously, and the cornea loses its natural brilliancy, and becomes dull and hazy,—the surface appearing as if covered with fine dust, or resembling glass that has been breathed upon; and, at a later period of the disease, it seems studded with minute depressions. The fine vessels of the conjunctiva and sclerotica become injected;—those of the sclerotica, which is the principal seat of increased vascularity, being arranged in radii around the cornea, and presenting a carmine hue: occasionally, too, the

vessels are so numerous over the corneal epidermis, as to form a vascular network, which covers the entire surface, and has been termed *pannus*. The pain attending inflammation of the cornea, may be acute in the early stage, and be accompanied by photophobia and by lachrymation. As in other cases, too, it may come on in paroxysms. In the chronic stage, it is not violent; often, indeed, it is slight.

The terminations may be like those of other forms of ophthalmia,—for example, interstitial deposition; ulceration; protrusion of the iris; obliteration of the pupil; immobility of the iris; adhesion of the iris to the cornea, &c. &c.

In all cases, the prognosis ought to be guarded; yet, division of the membrane by the knife generally heals without any inconvenience, as in the operation for cataract by extraction; and in cases of penetrating and other wounds of the cornea, we often see surprising recoveries.

Treatment.—In this there is nothing peculiar. The general management, advised under simple and strumous inflammation of the conjunctiva, is equally appropriate here. Full antiphlogistic measures may be required in the acute stage; but it must be borne in mind, that the inflammation is apt to pass into the chronic form; when revellents—as blisters behind the ears, occasional cupping on the nape of the neck, and mercury administered so as to produce a revellent impression on the mouth, with or without tonics, as the case may seem to require, will be most serviceable. The internal use of the oleum terebinthinæ, (gtt. xx.—xxx. ter die,) has been found serviceable in the strumous form.

Where the ceratitis is of some standing, it is commonly accompanied by increased secretion of the aqueous humour, so that the cornea becomes more convex than natural. In such case, it has been proposed to evacuate the humour by puncturing the cornea, with the view of relieving the painful sense of distension; and it is said to have been practised with advantage by several practitioners.

Sulphate of quinia, in conjunction with collyria of nitrate of silver or sulphate of zinc, according to Dr. Littell, (*A Manual of the Diseases of the Eye*, p. 123, Philad. 1837,) evinces frequently a remarkable control over vascular albugo, or that form of the disease which is characterized by lymphatic deposition.

Inflammation of the Iris.—The iris may be inflamed in consequence of the extension of inflammation from other parts of the eye, but it may be inflamed also idiopathically; and again, the inflammation may be modified according to syphilitic, arthritic, or other complications. Hence, various divisions of iritis have been made; but these are scarcely necessary, inasmuch as they are indicated only by a knowledge of the history of the case, or a careful examination of the patient.

Diagnosis.—Inflammation of the iris, whatever may be its cause or complication, presents certain phenomena, some of which belong to itself; others are common to it and to other forms of ophthalmia.

Those that belong to the iris are loss of its usual brilliancy, and change of colour. This change is the result of a combination of the natural colour of the iris with red blood, red blood and yellow lymph mixed, or yellow lymph alone.

If the inflammation be seated in the serous covering of the iris—*Iritis serosa*—the colour is not changed, but is modified by the appearance of a pale grayish coat, which gives a dull aspect to the membrane. In serous iritis, consequently, a blue iris may remain blue; but the colour is rendered dull. The structure of the iris also exhibits change; its fibrous texture is no longer observable, and tubercles or abscesses may form in its substance. It also loses its contractility, so that the pupil remains unchanged in size when exposed to different degrees of light, and is generally contracted.

Along with these pathognomonic symptoms are many which belong both to it and to other inflammations of the eye. Thus, there is zonular redness of the sclerotica, produced by numerous vessels surrounding the cornea, and running towards its edge: adhesions may also form between the iris at its pupillary margin, and the capsule of the crystalline; and, in rare cases, it adheres to the posterior surface of the cornea, and more or less plastic lymph is effused into the anterior or posterior chamber of the eye, or into both, giving rise to imperfection of vision, and, at times, to total blindness. Photophobia, lachrymation, and deep-seated circumorbital pain, generally aggravated at night, are present to a greater or less degree, according to the severity of the inflammation. The constitutional disturbance is often very considerable, and the symptoms proceed at times so rapidly, that vision is destroyed in a few days.

Such are the main phenomena of iritis, whatever may be the cause or complication.

Causes.—Along with mechanical injuries, and other agencies concerned in the production of ophthalmia in general, may be reckoned,—a constitutional predisposition given by syphilis and scrofula, and, perhaps also by gout and rheumatism; hence we have, in many works,—*acute idiopathic iritis*, *syphilitic iritis*, *rheumatic iritis*, *arthritic iritis* and *strumous iritis*, as so many subdivisions.

Treatment.—The first object in a case of iritis is to subdue the inflammatory action, and prevent the effusion of lymph. General bloodletting should be prescribed immediately, and be repeated according to circumstances; blood may, at the same time, be taken from the nape of the neck by cupping; and, along with this, cathartics, nauseating doses of tartrate of antimony and potassa, and the whole antiphlogistic treatment and regimen advised under the most acute forms of ophthalmia already considered, must be directed. Where the disease is less severe, and the constitution of the individual such as to render it advisable to be cautious in the abstraction of blood from the general system, cupping may be trusted to, along with the general management and regimen already inculcated.

The most approved method of treatment—after bloodletting has been practised—is to administer mercury so as to induce a revellent influence on the system, under which effusions of plastic lymph are prevented,—or removed, if they already exist.

℞.—Hydrarg. chlorid. mit. gr. xij.
Opii. pulv. gr. iij.
Glycyrrhiz. pulv. ℈ss.
Confect. rosæ. q. s. ut fiant pil. xij.
Dose, one, every four hours.

The effect upon the system is sufficiently evidenced by its *touching* the mouth. In some cases, in which full salivation supervened, it appears, according to Dr. Taylor, (*Tweedie's Library of Medicine*, 2d Amer. edit. ii. 162, Philad. 1842,) to have acted like a charm. Still, so many inconveniences are induced by ptyalism from mercury, that the remedy should not be pushed to this extent, if the disease will yield without it; and especial care should be taken on this head, if the iritis be accompanied by a strumous constitution. In such case, mercury may still be demanded, but it should be administered if possible so as only to affect the constitution gently, and its agency be kept up for a length of time. Should salivation supervene in any form of iritis, no farther good can, of course, result from the mercury, until its effects have subsided.

To relieve the circumorbital pain, frictions with any of the liniments recommended in the other forms of ophthalmia may be had recourse to. An ointment, combining a mercurial with an opiate, has been strongly recommended.

Collyria are of little or no benefit; and the various counter-irritants, employed in ophthalmia, are of service only after bloodletting has been actively premised. Oil of turpentine has been extolled as an internal revellent, where mercury is inadmissible.

To prevent contraction of the pupil, extract of belladonna may be smeared over the eyebrow once in twenty-four hours, or a filtered aqueous solution may be dropped on the conjunctiva. When cautiously employed, it gradually elongates the filaments of lymph that have formed between the iris and the capsule of the lens; and, with this view, its use may have to be continued for months.

In the iritis, which occurs in a constitution contaminated by the syphilitic poison, as well as in the other forms referred to,—the same general principles of treatment apply, and but slight modification is necessary. In the rheumatic, arthritic, strumous, and more chronic forms of idiopathic iritis, sulphate of quinia is often beneficial, but it should not interfere with the other appropriate remedies, and especially with calomel and opium.

Inflammation of the Choroid.—As an accompaniment of inflammation of other parts of the eye, choroiditis has been admitted by all writers on the subject; but it has not been described by all as an independent disease.

Diagnosis.—The following have been depicted as the functional phenomena of inflammation of the choroid. One of the earliest symptoms is the formation of a blue zone around the cornea: this is produced by thinning of the sclerotica, which is succeeded by the protrusion of small tumours of a dark bluish colour, varying in size, number and position; a watery effusion forms gradually between the choroid and the retina, which produces absorption of the vitreous humour, and compresses the retina into a cord-like substance, simulating the appearance of deep-seated cataract or malignant tumour of the optic nerve. The pupil is often altered in shape, the iris immovable, and the cornea opaque; these symptoms arising from the simultaneous inflammation of those various parts. Enlargement of the globe of the eye likewise results at times, and morbid changes, which may render the extirpation of the organ necessary. There is always more or less pain and intolerance of light; but the constitutional symptoms are generally inconsiderable.

Causes.—Of these we know little. It is a disease of the adult age, and is said to be more frequent in females than in males, and especially in those of a strumous habit.

Treatment.—This does not vary from that recommended in iritis. Mercury does not, however, seem to be decidedly beneficial. After active depletion, tonics, as sulphate of quinia, have been found of great benefit, and as the disease frequently occurs in strumous habits, their use is generally indicated. The arsenite of potassa (*Liq. potass. arsenit.* gtt. v.—viij. ter die) has been advised by Mackenzie: (*Practical Treatise on Diseases of the Eye*, 3d edit., 1840.) The morbid appearances in the advanced stage, it is affirmed, have disappeared under its use, and health and vision have been restored simultaneously.

When the eye-ball is tense and painful, and there is a tendency to choroid staphyloma, puncturing the sclerotica and choroid, so as to evacuate the contained fluid, has afforded relief.

Inflammation of the Retina.—This is an uncommon affection, except as an accompaniment of other forms of ophthalmia.

Diagnosis.—As the retina cannot be seen, the existence of retinitis has to be inferred from disturbance of function. The intolerance of light is great; shining spectra, of various kinds, are seen, and there is a gradual impairment of vision; the iris is motionless, and the pupil greatly contracted, whilst the whole globe is highly sensible to the slightest touch or movement. These symptoms are usually accompanied by deep-seated pain in the globe of the eye, which extends to the eyebrow, and is often very severe, and accompanied by symptoms of cephalitis. When the disease is acute, the febrile excitement is often very great.

Extensive disorganization of the internal structures of the eye-ball is a common result; and purulent effusion sometimes takes place, which may augment to such a degree that the cornea gives way, the pus is discharged, and the eye-ball collapses.

Acute inflammation of the retina is less seen than the chronic form, which is characterized by intolerance of light, of different degrees; impaired vision, with ocular spectra, and, ultimately, by immobility of the iris. It has been considered one of the most common causes of amaurosis, and requires the revellent treatment recommended under that disease.

OSSIFICATION. See Tissues, Adventitious.

OTALGIA and OTITIS, (from οὖς, *auris*, gen. ὠτὸς, and ἀλγέω, *doleo*.) Ear-ach; pain in the ear. The ear-ach, which on all occasions results from a morbid congestion of some part of the organ of hearing, cannot be intelligibly explained

without first considering the affections of which it is a symptom; and as the diseases of the ear have not yet been spoken of in this work, it is proposed to give a concise account of them in the present article.

Until the publication in 1821 of the admirable *Treatise on the Ear*, by M. Itard, of Paris, physician to the Royal Institution for the Deaf and Dumb, the profession was in a deplorable state of ignorance respecting the pathology of this organ; an ignorance which has been lamented by every author who has taken up or happened to allude to the subject. The situation of the organ deep in the skull, the intricacy of its general structure, the minuteness of its various parts, added to the difficulty of tracing them in their bony case, and the supposed obscurity and unmanageable nature of its diseases, have all contributed to deter professional men from bestowing their attention, as well upon the anatomy as upon the pathology of the ear; and the consequence is a deplorable want of knowledge on these subjects. This is the less excusable, since the work of Itard affords a very complete and masterly account, not only of the diseases, but of the anatomy and physiology of the organ. Itard, indeed, whose treatise cannot be too highly praised, has done for the organ of hearing what the illustrious Laennec has done for the organs of respiration: and yet so little known in this country are the labours of this author, that in a small volume just now published on "The Organ of Hearing," we do not find the name of Itard quoted. The writer's attention was particularly called to the ear many years since by the occurrence of cases of chronic disease of the tympanum producing a purulent discharge from the external meatus, penetrating the skull, and destroying the individuals by disorganization of the brain. Subsequent experience has only tended to confirm the interesting and important nature of the subject; and it is with some degree of confidence, therefore, that we invite the members of the profession to study this department of pathology. We can assure them that the path which may appear intricate and impracticable, is so only because it is untrodden and unfrequented.

The diseases of the ear may be conveniently arranged, according to the anatomical division of the organ, into those which are seated respectively in the external, the middle, and the internal parts of the ear.

The diseases of the middle ear are the ordinary cause of otalgia, strictly so called; on which account, as well as because they are the most frequent and formidable, we shall enter upon the consideration of them in the first place.

1. The middle ear comprehends the cavity of the tympanum, with its contained chain of ossicula, its proper membrana tympani and its dependencies, the mastoid cells and Eustachian tube; all which parts, lined with a mucous membrane, present an extensive continuous surface, apt to be involved in the affections of the tympanum. Of the five openings leading to and from the tympanum, three are closed, the fenestra ovalis and fenestra rotunda by their proper membranes, the large opening to the external meatus by the membrana tympani; while the other two are open, the one leading to the Eustachian tube, the other to the mastoid cells,—which cells, forming as they do a cul-de-sac, leave the Eustachian tube the only open channel of communication with the tympanum from without. Hence it happens that in inflammation of this cavity, it and the mastoid cells become filled with the usual product of inflammation of a mucous membrane, a muco-purulent effusion, which has no means of exit, because the Eustachian tube, the only channel by which it could escape, is involved in the inflammation and closed by it. In this manner the delicate fabric of the ear is exposed to the pressure and other bad effects resulting from matter confined in a close cavity; and hence arise ulcerative perforation of the membrana tympani, puriform discharge from the meatus externus, destruction of the organ by caries, and eventually cerebral abscess and death.

The inflammation of the cavity of the tympanum, like the inflammations of the other parts of the body, may be intense, or it may be subacute.

a. The subacute internal otitis is an affair of common occurrence, and constitutes the pathological condition of nearly all of those cases which pass under the denomination of ear-ach. The patient complains of pain in the ear, perhaps of the head in some degree, accompanied with singing noises and dulness of hearing. There may be a slight impairment of the appetite, which appears to arise rather from the pain than from any febrile movement, the sanguiferous system and the organic functions scarcely sympathizing in this affection. In the corresponding side of the head there is a susceptibility to the impression of a cold atmosphere, which induces the patient to wrap up the head; with this precaution he is content to bear the pain for several days, when it usually subsides, leaving the sense of hearing less acute for a short period; after which the organ soon recovers itself, and the affair is ended.

b. Very opposite to this are the symptoms, progress, and termination of the acute internal otitis, or intense inflammation of the tympanum. This inflammation is characterized by an intense, acute, unremitting pain, deep-seated in the ear, attended with loud, clanging, metallic noises, the pain affecting the whole head, but in an especial manner the side corresponding with the seat of the inflammation. As the inflammation attains its height, so does the pain in the ear become distracting, and excites nocturnal delirium; and with this dreadful pain is a sense of violent distension, as if the part were on the point of bursting. The pain of the head is proportionably aggravated, and attended with heaviness and weight. The face manifests great anxiety and distress; the constitution sympathizes deeply, but the character of this sympathy is less marked by the high febrile movement which usually accompanies inflammation, than by great general exhaustion, the effect of continued pain. The pulse is frequent, but not remarkable for fulness or strength, nor is there much increase of heat; nevertheless all the organic functions are troubled, and the tongue is furred, the taste vitiated, and the appetite lost.

This state of things having persisted for twenty-four or thirty-six hours, the inflammation begins to decline, the pain to diminish in intensity, and the metallic noises change to a violent hissing;

the sense of distention and of bursting continues though in a less degree, but the delirum passes away, and the pain and uneasy sensations of the head gradually subside. The taste and appetite return quickly, and the patient is soon convalescent; though the hissing in the ear and the sense of distension and bursting are troublesome for two or three weeks, and various noises are perceived occasionally for some months. The organ, however, recovers its proper function, but slowly; the patient experiencing an indistinctness of hearing, often of sight, for a considerable period.

Such is the happiest termination of an acute inflammation of the middle ear.

Instead of this termination in resolution, if the violent symptoms, present at the height of the inflammation, do not abate, the sense of distension increases to a most painful degree, the general headach continues urgent, and the delirium manifests itself at times by day as well as at night, and in the course of two or three days matter is observed to discharge from the ear. In this case the cavity of the tympanum has become filled by a puriform fluid, the product of the inflammation, which has effected a passage by ulceration through the membrana tympani, and is discharging itself by this channel.

Should the perforation of the tympanum be large, and the discharge free and copious, then the fever and other urgent symptoms quickly subside, and a chronic puriform discharge, the *otorrhœa purulenta*, is established. Should the perforation be small and the discharge trifling, it proves insufficient to relieve the sufferings of the patient; the distressing signs of matter confined in the middle ear continue; and now it becomes the duty of the practitioner to recommend an operation to enlarge the opening in the membrana tympani. If a free outlet is thus accomplished, complete relief is afforded; the puriform discharge becomes abundant; and, as in the former case, an otorrhœa is established.

The establishment of the purulent otorrhœa is not always preceded by a form of inflammation so acute as that described; it is often brought about gradually by a subacute otitis of a chronic kind, in which case the symptoms are less severe, are more confined to the ear itself, and the perforation of the membrana tympani is slowly effected. This consecutive affection deserves further notice.

[It may happen, that the abscess, when it breaks, is discharged through the Eustachian tube into the throat. According to one observer, M. Itard (*Mém. de l'Académ. Royal de Méd.*, tom. v. fasc. iv. Paris, 1836,) this occurs in about one case in ten. The patient feels the pus passing down the tube, and ejects it at times in considerable quantity.

The lining membrane of the cavity of the tympanum is fibro-mucous,—or at once a mucous membrane, and a periosteum; and it has been observed, that the membrane has been the seat of a blennorrhœal inflammation in its outer layer, and of a more violent inflammation, like the one described above, in its inner layer. In the former case, the mucus may be secreted in such quantity as to impede the entrance of air through the Eustachian tube into the middle ear, and thus cause deafness. Where the mucus exists in any quantity in the middle ear, it may be detected by catheterism of the Eustachian tube, which has, accordingly, been employed not only in the way of diagnosis, but of therapeutics. Air *douches* are used for this purpose by means of an apparatus, which the writer has described elsewhere; different sounds being rendered according to the precise condition of the cavity. (Deleau, *Sur le Catheterisme de la Trompe d'Eustache*, Paris, 1828: Itard, *Op. cit.*: Kramer, *On Diseases of the Ear*, Amer. Med. Lib. edit. Philad. 1838; or the writer's *New Remedies*, 4th edit. p. 366, Philad. 1843.]

Otorrhœa Purulenta, a purulent discharge from the external meatus, may arise from some disease of the meatus itself as a porriginous affection of the lining membrane of the tube; in this case the affection is of little importance. The otorrhœa about to be described proceeds from the middle ear, is the result of a suppurative inflammation of the tympanum with perforation of the membrana tympani, and is a very serious complaint. Inflammations of the tympanum having terminated in suppuration, and the matter having worked itself an outlet, it may be reasonably supposed that all diseased action would subside and cease; and such, no doubt, would be the favourable issue, were it not that, from the peculiar conformation of the organ, part of the matter is retained in the cavity of the tympanum and mastoid cells, and thus becomes a cause of extensive mischief.

The opening of the Eustachian tube being situated at the anterior and internal angle of the floor of the tympanum, may appear to offer a natural and depending outlet to the retained matter; but this channel is either closed altogether or much obstructed by its lining membrane having been involved in the inflammation; and although a free outlet may have been formed by the perforation of the membrana tympani, yet some matter is still retained in the cavity and in the mastoid cells. It is retained in the latter because they form a blind irregular cavity; and in the tympanum because of the peculiar form of the meatus externus, which being arched, and having the crown of the arch on a level with the middle of the tympanum, resists rather than favours the spontaneous emptying of the cavity. Under these circumstances the matter lodges in the tympanum as in a well, and gives rise to a train of formidable symptoms which constitute the second stage of the disease.

The perforation of the membrana tympani giving access to the air, the retained matter undergoes decomposition, becomes highly irritating, and induces ulceration of the lining membrane of the tympanum and mastoid cells; the osseous structure is now exposed to the influence of this irritating matter, and a carious disorganization commences. The insidious advance of the caries is indicated by a dull pain seated principally in the region of the middle ear, but diffusing itself over the corresponding side of the head, by the sense of hearing being blunted, and by a dull and rather vacant expression of the countenance.

The disorganization proceeds more rapidly in the mastoid cells than in the tympanum, because of their less compact structure, and is made apparent by the mastoid process becoming tender on

pressure, and the integuments puffy and vascular; by-and-bye the perforation of the bone is completed, and an abscess manifests itself behind the ear. The point where the carious perforation happens is usually at the anterior part of the groove which gives origin to the digastric muscle. The abscess does not burst readily, but extends itself upwards behind the ear, the soft parts offering less resistance in this direction; examples, however, occur, in which the abscess directs itself downwards under the sterno-mastoideus when it points low in the neck; it never extends backwards, because of the resistance of the digastric and trachelo-mastoid muscles and of the deep cervical fascia.

The caries of the mastoid cells is not limited to this outward direction, but extends on every side, and next affects the posterior wall of the cells, and perforates the petrous portion of the temporal bone which forms the fossa of the lateral sinus: the bone is here naturally thin, and, when carious, presents a worm-eaten appearance. Through these carious perforations the matter penetrates, and by irritating and detaching the dura mater, gives rise to decided cerebral symptoms. The same process sometimes goes on in the roof of the mastoid cells formed by the superior surface of the petrous portion; but the bone being here thicker is less easily perforated. Should the patient still live, the caries will destroy the chain of ossicula in the tympanum, and they will be discharged through the external meatus; eventually the caries will ravage the whole internal ear, destroying the membranes which close the fenestra ovalis and the fenestra rotunda, and disorganizing the vestibule, semicircular canals, and scalæ of the cochlea. In this way all the sinuosities and cavities and bony fabric of the ear are broken down and confounded together, and the interior of the petrous portion and of the mastoid process of the temporal bone presents one large carious excavation.

To such an extent did the disorganization proceed in the case of a child two years and a half old, that the entire labyrinth, consisting of the semicircular canals and cochlea, was discharged by the meatus externus. In this instance the course of the disease was marked by the various stages of inflammation of the internal ear, succeeded by the chronic puriform discharge, by the dislodgement and evacuation of the ossicula of the tympanum, and, lastly, by the coming away of the labyrinth itself through the meatus externus, occupying in the whole a period of several months. (This case is detailed more at length in Mr. Tod's work on the "Organ of Hearing," p. 134.)

In the course of the devastation above described, the portio dura becomes also involved, and the disorganization of this nerve gives rise to neuralgic pains, convulsive twitchings, and paralysis of the muscles of the corresponding side of the face.

At the period when, in the progressive caries of the temporal bone, the dura mater becomes exposed to the irritation of the corrupt secretion from the ear, the membrane inflames and suppurates, and becomes detached by the matter burrowing between it and the skull; the patient is then sometimes carried off at once by meningitis, or the destructive process may proceed and induce ulceration of the dura mater and other membranes, and, finally, of the brain itself. The ulceration of the brain may be superficial, or may penetrate deep into its substance and form a suppurating cavity, having the aspect of an abscess, which will in some cases occupy the whole of the middle lobe of the corresponding hemisphere, or the corresponding lobe of the cerebellum.

While the disease is confined to the ear, the sympathetic pain in the head radiating from this organ is the most marked symptom; but as soon as the membranes of the brain become involved, the cerebral signs predominate and obscure the original disease. The patient, who probably hitherto has been in the hands of the aurist, is now transferred to the care of the physician, who, finding the signs of cerebral disease marked and decided, will often fail to trace them back to the ear as their origin, and therefore regards the case as an idiopathic cerebral affection. Nor is the error always cleared up by dissection, because the morbid appearances in the brain present a satisfactory cause for the violent symptoms and fatal termination, and the caries of the temporal bone, which is less conspicuous on the cerebral surface, either escapes notice, or is concluded to be the effect of the cerebral disease. This, we are persuaded, is no uncommon case, having ourselves seen it happen to persons much accustomed to morbid dissection.

The slow carious disorganization of the ear may be a work of many years before it reaches the brain, during which period the puriform discharge from the external meatus varies much in quantity, particularly if the Eustachian tube is not altogether closed, the discharge being at one time profuse by the meatus externus, at another taking place by the tube into the throat. This latter effect is manifested by an offensive dark matter being mixed with the sputa, and which, collecting in the pharynx during sleep, is hawked up in the morning in considerable quantity. At times the discharge is suppressed, as when the patient takes cold in the ear; then otalgia supervenes, with headach and more or less of sympathetic fever, all which signs are relieved by a return of the discharge. Attacks of this nature are frequent.

The gradual disorganization is seldom attended with dangerous symptoms, so long as it is confined to the ear; but the moment it has reached the membranes of the brain, pain in the head becomes the prevailing symptom, and it is no longer referred to the ear as its cause. If now, from any accidental cause, the otorrhœa is suppressed, the patient experiences an inflammation of the membranes of the brain more or less severe; [*Cerebral Otorrhœa.*] The more extensive the disorganization, the more severe is the attack, and the more dangerous. Some patients survive many such attacks, and die exhausted by long suffering, while others are cut off by the attack which supervenes on the disease first penetrating to the dura mater. In this case, dissection will discover traces of inflammation of the detached membrane, with a little pus effused between it and the skull. A sympathetic but fatal inflammation of the membranes of the brain may occur at the period of the formation of the external abscess at the root of the

mastoid process, of which we have seen an example.

It is at one of these periods of the supervention of a meningitis that the physician is called in, and his first impression of the complaint, as we have already stated, is apt to favour the idea of an idiopathic inflammation of the brain, the patient and friends directing his attention to the cerebral signs without alluding to the affection of the ear, they themselves not being aware of their connection.

The **Diagnosis** in such cases is very important, inasmuch as the bloodletting required to save the patient in the one instance would destroy him in the other.

In the sympathetic inflammation of the membrane of the brain, in cases of otorrhœa, there are prominent local signs as regards the head; there is a deep-seated, severe throbbing pain in the middle of one side of the head, with great tenderness of the scalp on the same side, which prevents the patient lying upon it; there is no marked suffusion of the face and conjunctiva; the expression of the eye is rather dull; the delirium is little active, and is complicated with heaviness of the head, and some stupor; the fever is not severe in proportion to the local signs, nor is the force of the circulation great, the pulse being rather tight than full, and rather sharp than strong; the fever is moderate in the day, with a marked exacerbation at night.

In the idiopathic inflammation of the membranes of the brain, on the other hand, instead of local pain, there is a sense of constriction over the whole head, without tenderness of the scalp; the suffusion of the face and conjunctiva is very marked; the eye vivid, the delirium violent, without heaviness of the head or stupor; the fever runs high, and though it may have exacerbations, it is continually urgent, and the force of the circulation is decided, the pulse being full and strong.

These distinctions cannot fail to strike the physician, if he is cautious and circumspect in forming an opinion.

The **Cause** of the otorrhœa is invariably an inflammation of the tympanum, which may be excited by a current of air playing upon the side of the head, or may arise, as it more frequently does, from the spreading of inflammation by the sympathy of continuity from the throat along the Eustachian tube. Hence the origin of the disease is often referred to the period when the patient had the small-pox or scarlet fever. The deafness, which is a common consequence of the scarlet fever, is produced in this manner.

Treatment.—In speaking of the treatment of the affections of the ear, described in this article, viz., of the otalgia, the otitis interna, the otorrhœa, and of the occasional attacks of inflammation which supervene on the otorrhœa, all which affections are stages of the same disease, we cannot do better than retain the order already adopted, it being the one in which these stages naturally succeed each other.

It is scarcely necessary in this place to advert to the means of relieving the otalgia, or ear-ach, which has been shown to depend on inflammation of the tympanum, more or less acute; we shall therefore pass on at once to the treatment of the otitis interna, reserving what few remarks we have to offer on the cure of otalgia for the conclusion of this article.

Treatment of the Acute Internal Otitis.—This intense inflammation of the tympanum can be controlled only by very decided antiphlogistic measures, adopted without hesitation or delay, the object being to arrest the inflammation, and, by procuring its resolution, to prevent all those disastrous consequences which accrue from its termination in suppuration.

In detailing the symptoms of this otitis, we stated that the local signs of pain and so on were intense, while the general febrile movement, though fully developed, was not urgent in an equal degree; and as we hold it to be a principle in the treatment of all diseases, that the more the local signs exceed the general, the greater will be the relief from local depletion, we shall be guided by this principle in our recommendation of the treatment to be pursued. In place, therefore, of relying chiefly on the abstraction of blood from a vein, we urge the free and repeated application of leeches to the ear affected; premising, however, that one bloodletting should be practised to an extent consistent with the age, sex, constitution, and spare or plethoric habit of the patient. Let blood, then, be first drawn from the arm, or from the external jugular vein, which is preferable, to the amount of ten, fifteen, or twenty ounces, according to the circumstances above-mentioned, and, guided by the same circumstances, let it be followed up by leeches applied over the mastoid process of the ear affected, to the number of from six to eighteen. Repeat the application of leeches once in six hours at least; and that time may not be lost, let a blister be placed on the nape of the neck, which will leave the region of the ear free for the use of more leeches, if required. Fomentations can seldom be borne early in this inflammation; they accumulate heat, and aggravate the sufferings of the patient; nor is any medicament to be introduced into the external meatus for the same reason. In addition to the abstraction of blood, and to the counter-irritation, an active aperient, consisting of calomel and jalap, in the proportion of four grains and ten, or of a dose of calomel, quickly followed by a purging draught of ten drachms of infusion of senna and two drachms of tartrate of potash, should be administered; and in the course of four hours give one or two grains of calomel, with a quarter of a grain of tartarized antimony, every two hours through the first day, and every three or four hours through the second, when it will generally be necessary to omit the antimony, on account of the exhausted powers of the patient; the calomel to be continued in such quantity and as frequently as the then existing symptoms demand, remembering that, next to the abstraction of blood, our main reliance is to be placed on the mercury to procure the resolution of the inflammation. Opium is not admissible in any form or quantity; it distracts the patient.

If by this treatment the urgent signs should gradually abate and the inflammation pass away, the patient's appetite will quickly return, and a speedy convalescence be established. If, however, the symptoms do not yield to the vigorous treatment adopted, it is to be feared that suppuration

of the tympanum will ensue, which will be further indicated by the increase of the sense of bursting of the part, by the throbbing character of pain, the delirium, and general headach. Fomentations and poultices may now be had recourse to; the anti-inflammatory measures should be relinquished; and as soon as the ulcerative perforation of the membrana tympani has been effected, and the matter begins to discharge itself by the external meatus, the powers of the patient should be supported by ammonia, and sleep procured by opium.

If, with the discharge from the meatus, the throbbing pain, sense of distension, &c. do not manifestly and speedily subside, it is to be concluded that the perforation of the membrana tympani is too small to admit of the free exit of the matter, and an operation to enlarge the perforation is at once to be contemplated; and being effected, the sufferings arising from the matter hitherto confined in the cavity of the tympanum will be alleviated, a copious discharge ensured, and an otorrhœa established.

[In cases of *blennorrhœal otitis* of the middle ear, it has been advised that the air *douche* should be employed; and if a slight mucous *râle* be heard, on applying the ear to that of the patient, whilst the air is streaming in, followed by a material improvement in the hearing, which may be ascertained by the distance at which he hears the ticking of a watch, it has been advised, that it should be employed daily. Should no improvement, however, in the sense of hearing take place after the fourth sitting, it has been considered that the attempt should not be persisted in.

The careful introduction of the catheter into the Eustachian tube may be necessary in this variety.]

Treatment of the Otorrhœa.—In the foregoing part of this article, we have remarked the untractable nature of the chronic puriform discharge from the ear, and that its dangerous tendency depends on the decomposition and retention of the matter in the cavity of the tympanum, that cavity, owing to its peculiar construction, holding the matter as in a well. The indication, therefore, in the treatment is to prevent this lodgment of the irritating matter, and the manifest and only means of accomplishing this end is by cleansing the cavity of the tympanum by the aid of injections. As to the composition of the injections, it matters little; warm water or milk-and-water will answer the purpose as well as any thing more medicated. Care must be taken in the first use of the injection, which should be administered without much force until the parts are become habituated to it, otherwise a shock from the syringe might be very distressing to the patient. Should the discharge persist and become chronic, then astringent injections would be very proper. Itard recommends the caustic potass dissolved in rose-water. The sulphate of zinc offers a good remedy, so does the nitrate of silver; the proportions to be weak in the first instance, and increased in strength as circumstances indicate.

Although the injections may not be effectual in restraining or curing the otorrhœa, they have the power to counteract its destructive and dangerous tendency to disorganization, an apposite illustration of which we are able to furnish in the case of an old lady, now near seventy years of age, who has been affected with otorrhœa from both ears, and deafness, since she had the scarlet fever in childhood, and who, by the daily injection of warm water, has preserved the organs from further disorganization, and has escaped the disastrous effects and premature death which a progressive caries inevitably leads to.

[It is proper to remark, that it is extremely common to find persons pass through a long life, who have been subject, from infancy perhaps, to discharges from the middle ear, and who make use of no injections whatever. It is important, indeed, to be cautious in the use of astringent injections especially, where the otorrhœa has persisted long, inasmuch as a sudden suppression of the accustomed secretion — although morbid — may give occasion to the transference of the irritation elsewhere, and, it may happen, to parts of greater importance. In all cases, it is essential to attend to the constitutional condition, and if there be evidences of a strumous complication, as there often is, the tone of the system must be improved by remedies that are adapted for scrofulosis, and especially by the use of iodine — as the iodide of iron—singly or combined with appropriate diet, change of air, &c.

Where it is not considered advisable to interfere actively with the discharge, the disagreeable fœtor, as elsewhere remarked, may be very much diminished by appropriate injections of a disinfectant nature—as of weak solutions of chlorinated lime or chlorinated soda. (*Practice of Medicine*, 2d edit., ii. 361, Philad. 1844.)]

Treatment of the attacks of inflammation which occasionally supervene on the chronic otorrhœa.—The violence and danger of these attacks will be proportionate to the extent of the caries of the ear and the disorganization of the membranes of the brain at the period of their occurrence. While they affect the ear only, they need not excite alarm, because they subside in a few days by the application of leeches to the mastoid process, and by mild antiphlogistic measures. But when the disorganization has extended to the dura mater and brain, the inflammation affects these parts in common with the ear, and the symptoms assume a very formidable aspect. Yet it must be remembered that the cause of these attacks is the check given to the discharge either by cold or accidental obstruction, and that, therefore, the symptoms of the cerebral affection are more or less sympathetic, and partake of those of irritation. There is a train of actions set up in the brain depending on a local cause, which cause being done away, the undue actions subside. For this reason every means must be sedulously adopted to encourage a return of the discharge, as fomentations and poultices to the side of the head, and bloodletting must be employed only so far as to restrain the inflammation within limits consistent with life; for if blood is drawn ever so freely, it cannot put an end to the attack, as in an idiopathic meningitis, and it will sink the patient as soon as the discharge returns. In these cases mercury is not required; it is worse than useless if carried to any extent. In every attack of this nature the practitioner should not neglect to examine the affected side of the head attentively, as such an attack is apt to super-

vene at the period of the formation of an abscess behind the ear from the carious perforation of the mastoid process. Should an abscess be discovered in this situation, a very free perpendicular incision is to be made, not only down to the process, but through the carious walls of the process itself into the cells, and relief will be immediately afforded to the cerebral symptoms. The writer was once called to a case of this description, which had been viewed and treated as an idiopathic phrenitis, when he discovered a large abscess presenting behind the ear; it was opened, and discharged a quantity of most offensive pus. The patient was relieved, but she sunk from the copious bloodlettings practised under the erroneous diagnosis of cerebral inflammation.

In one case in which a free opening was made into the mastoid cells by incision, as we have advised, a spontaneous cure of the otorrhœa followed.

The administration of injections in the chronic otorrhœa must not be adopted without some precaution; not without first estimating the extent of the carious disorganization; for should this have penetrated the skull, and a fluid be forced into contact with the dura mater, or this being ulcerated, into contact with the brain, a fatal inflammation would be the result. The extent of the disorganization may be determined correctly by the character of the symptoms. While the disease has not extended beyond the ear, the sufferings are referred to this organ by the patient, the pain being deep seated in the ear, and radiating from it over the side of the head; but as soon as the dura mater and brain are involved, the signs of cerebral affection predominate, the complaints now being all referred to the brain. This diagnosis will be a safe guide, and should be borne in mind. The disease being limited to the ear, will be benefited by the use of injections, and further mischief may by them be probably guarded against; but when it has reached the brain, injections are not justifiable.

The treatment of the otalgia does not call for any particular measures further than such as are appropriate to the relief of the inflammation, be it subacute or acute, of which the otalgia is a sign. The remarks it is of consequence here to make are, that the otalgia, or ear-ach, is indicative of an inflammatory congestion of the tympanum, which should not be neglected however trivial it may appear. Though the patient may not estimate the importance of an ear-ach, the practitioner should do so, and not be content until he has removed it by the application of leeches to the mastoid process, by aperients and so forth; not trusting to popular remedies placed in the meatus, but rejecting them; and taking a proper pathological view of the nature of the affection, of the dependence of otalgia on inflammation of the tympanum, he should combat it by appropriate remedies accordingly, and so preserve the patient from impairment of the sense of hearing, or from that disorganization of the ear of which even a very subacute otitis may be the unsuspected forerunner.

JOHN BURNE.

OVARIA, DISEASES OF THE.

I. OF THE STRUCTURE AND FUNCTIONS OF THE OVARIA.—In the human subject, after the age of puberty, the ovaria form two oblong flattened bodies, about an inch and a half in length, which are situated on the sides of the uterus in the posterior duplicatures of the broad ligaments. They are placed a little below the fallopian tubes, near the superior angles of the uterus, to which they are fixed by a short ligament. Their surface, except at the inferior margin where the blood-vessels enter, is smooth and convex. In the fœtus at the full period, the ovaria form long, slender bodies of a prismatic form, and are placed above the brim of the pelvis. In advanced life, they become hard and shrivelled, with deep irregular fissures in their surface.

Each ovarium consists of a peritoneal coat, and a dense fibrous or parenchymatous structure. In this latter texture are imbedded from twelve to twenty vesicular bodies of various sizes, which are named, from their supposed discoverer, the Graafian Vesicles, or Ovula Graafiana. They are composed of a fine membrane, which is separable into two layers, and contain within their cavity a clear coagulable fluid.

Branches of the spermatic arteries and veins are distributed to the ovaria, and they are also abundantly supplied by nerves and absorbents.

The remarkable changes produced in the intellectual and physical constitution of women, at the age of puberty, by the development of the ovaria, have been accurately described by Harvey in the following passage: "nec minus notum est, quanta virgini alteratio contingat, increscente primum et tepefacto utero; pubescet nempe, coloratior evadit, mammæ protuberant, pulchrior vultus renidet, splendent oculi, vox canora, incessus, gestus, sermo, omnia decora fiunt."

There are certain facts which seem to prove that it is not to the influence of the uterus, but of the ovaria that we are to attribute all the changes which take place in the female pelvis, in the mammæ and uterine system, at the period of puberty; and it seems not improbable from the following facts, that it is also to certain changes in the Graafian vesicles at the time of menstruation, that all the phenomena of that singular process are to be referred.

The case of a young woman who died at the age of twenty-nine, in whom the ovaria were wanting, was published by Mr. Charles Pears, in the second part of the Transactions of the Royal Society of London for 1805, and the following appearances have been recorded. "Having ceased to grow at ten years of age, she was in stature not more than four feet six inches high. The breadth across the shoulders was as much as fourteen inches, but her pelvis measured only nine inches from the ossa ilia to the sacrum. Her breasts and nipples never enlarged more than in the male subject. She never menstruated; there was no appearance of hair on the pubis, nor were there any indications of puberty in mind or body at twenty-nine years of age."

In the young woman, whose ovaria were extirpated by Mr. Pott in an operation for inguinal hernia, menstruation ceased, the voice became hoarse, the mammæ shrunk, and hair appeared on

the chin and upper lip. Before this period this female was stout, large breasted, and menstruated regularly. (Pott's Works, vol. ii. p. 210.)

Mr. Yarrel has shown that where there is a shrinking and shrivelling of the ovaria from disease in young birds, the hen bird assumes in many instances the plumage of the male. "Thus, in several mules (hen birds with male plumage) the ovarium has been found variously diseased; sometimes the oviducts appear to have been inflamed, and adhesions to have taken place between their opposite sides, so that they become obliterated; at other times the ovaria are shrivelled and of a black colour, and appear as if they had never been in progress to maturity. This black colour also pervades the oviduct, which is smaller than natural, and often impervious in some parts. In old birds it might fairly have been alleged that the destruction of the ovarium and the change of plumage followed only the general obliteration induced by age, and that the one was not dependent on the other; but the fact that destruction by disease of the ovarium in the young bird induces a similar change, and the destruction of the oviduct by art being followed by an alteration incomplete indeed, but in many respects resembling the one mentioned, sets the question at rest." (Dr. Seymour's Illustrations of Diseases of the Ovaria, 8vo. 1830, p. 36.)

Dr. Elliotson related to the writer of this article the history of the following interesting case, which came under his notice upwards of ten years ago. "A young woman," he says, "consulted me for amenorrhœa; she had never menstruated, and yet had violent pains every month. I strongly suspected there was some organic disease, and wished to obtain permission to examine, but to this she would not consent, and did not return to me for a considerable period. She informed me when she again consulted me, that she had been married for a year, but had never menstruated. I then thought I must have been wrong, and that there was no organic cause. I asked if she was happy with her husband, and from her answer concluded that sexual intercourse went on. The husband afterwards came to me and stated that he had not encountered any impediment to connection, but that he gave her violent pain at the time. I afterwards was permitted to examine, and then found there was no vagina; the part on opening the labia being as flat as the palm of my hand. She had most excruciating pains in the pelvis every month; there was every symptom of menstruation except the discharge. At my desire she was examined by Mr. Henry Cline, who plunged a lancet between the labia, but found nothing. She went on with these monthly pains, which she had experienced ever since puberty, and her life was rendered utterly wretched. I begged Mr. Cline to make another attempt, and he put in a bistoury as far as he dared go, but found nothing. Every sort of examination was afterwards made, and no uterus could be discovered. She remained several years in this situation, when her husband died and she has married again. Though there was no uterus, it was evident from the appearance of the mammæ and other circumstances, that the ovaria had been fully developed."

Through the kindness of Mr. Girdwood, of Paddington, we had an opportunity in 1831 of seeing a case in many respects similar to the preceding, in which there appeared to be a deficiency of the uterus, and an effort at menstruation every monthly period. The patient was twenty-five years of age, and had been married two years, though she had never menstruated. Every month there was great pain in the region of the pelvis, which lasted for several days and then went off, without any menstrual discharge taking place. The mammæ and external sexual organs were fully developed. On examination at the posterior part of the vagina, the finger readily passed into a short cul-de-sac about an inch and a half in length. From ocular inspection, it was evident that this cul-de-sac did not reach the meatus urinarius, but between them was a narrow opening which admitted the catheter, and which could be passed up four or five inches. This canal was gradually dilated so as to admit the finger the whole length, but not the slightest trace of a body like the uterus existed at its upper extremity.

Mr. Cæsar Hawkins has related to us the case of a woman who had the vagina and uterus completely obstructed after parturition, and in whom there was a monthly effort at menstruation, though no menstrual fluid was secreted. No swelling of the abdomen took place; and though incisions were made through the vagina into the uterus, no fluid escaped.

In Beck's Medical Jurisprudence, somewhat similar cases are referred to.

On the 11th of March, 1831, we examined the body of a young woman who died during menstruation from inflammation of the median basilic vein. The left ovarium was larger than the right, and at one point a small circular opening with thin irregular edges was observed in the peritoneal coat, which led to a cavity of no great depth in the ovarium. Around the opening, to an extent of three or four lines, the surface of the ovarium was of a bright red colour, and considerably elevated above the surrounding part of the peritoneal coat. On cutting into the ovarium, its substance around the opening and depression was vascular, and several Graafian vesicles of different sizes were observed. The right ovarium was in the ordinary state. Both fallopian tubes were intensely red and swollen, and their cavities were filled with menstrual fluid. The lining membrane of the uterus was coated with the same fluid, and the parietes were soft and vascular. The size of the uterus was not increased.

In the autumn of the same year a woman, under twenty years of age, died suddenly from acute inflammation of the lungs while menstruating. The body was examined by Mr. John Prout, and the uterine organs were brought to us for inspection. A red, soft, elevated portion of the right ovarium was also here observed, and at one part the peritoneal coat to a small extent had been removed. The edges of the opening were extremely thin and irregular, and in the substance of the ovarium under the opening was an enlarged Graafian vesicle, filled with transparent fluid. Numerous small blood-vessels were seen running along the peritoneal coat of the ovary to the opening. When the substance of the ovarium was laid open, several vesicles of various sizes, and a

different depths, were found imbedded in it. The left ovarium presented a natural appearance. The free extremities of the fallopian tubes were gorged with blood. Their cavities were filled with a red coloured fluid. The uterus was not enlarged, but the parietes were gorged with blood, and the lining membrane of the fundus was coated with menstrual fluid. A small coagulum of blood likewise adhered to the upper part of the uterus.

On the 2d of July, 1832, Sir Astley Cooper, to whom the writer had mentioned these cases, sent him the ovarium of a woman who died from cholera while menstruating. The ovarium was much larger than natural, and at one point there was a small irregular aperture in its peritoneal coat, through which a portion of a slender coagulum of blood was suspended. On cutting into the substance of the ovarium, it was found to be occupied by three small cavities or cysts, one of which was filled with a clear ropy fluid, another with semi-fluid blood, and the third, which communicated with the opening in the peritoneal coat of the ovarium, with a firm coagulum.

On the 18th of November, 1832, the uterine organs were removed by Messrs. Girdwood and Webster, from the body of a young woman who had died suddenly the preceding day when the catamenia were flowing. Both ovaria were remarkably large, and both fallopian tubes were red and turgid. The peritoneal coat of the left ovarium was perforated at that extremity which was nearest to the uterus by a circular opening, around which aperture for several lines the surface of the ovarium was elevated and of a bright scarlet colour, like extravasated injection. The margin of this opening was thin and smooth, and did not appear to have been produced by laceration. Its centre was slightly depressed below the level of the edges, but there was scarcely the appearance of a cavity beneath. The right ovarium was much larger than the left; and when cut into, a cavity or cyst was found which was filled with half coagulated blood. The peritoneal coat of this ovarium was entire.

The uterus was large, and when cut into, the parietes appeared to contain an unusual quantity of blood. The inner membrane was of a bright red colour, and coated with a thin layer of catamenial fluid. Both fallopian tubes were red and turgid, and the interior of the left was filled with menstrual fluid, but nothing in the form of a Graafian vesicle could be detected in the tube. The appearances now described have been accurately represented in a drawing made from the parts within two hours after they came into the author's possession.

In a paper by Mr. Cruikshanks, published in 1797, there is an account of similar appearances having been observed by him in a young woman who had died at the monthly period. "I have also," he says, "in my possession the uterus and ovaria of a young woman who died with the menses upon her. The external membranes of the ovary were burst at one place, from whence I suspect an ovum escaped, descended through the tube to the uterus, and was washed off by the menstrual blood."

Dr. Power has likewise conjectured that an ovum escaping from the ovarium at every monthly period is the cause of menstruation, which he has defined to be "an imperfect or disappointed action of the uterus in the formation of the membrane (decidua,) which is requisite for its connection with the impregnated ovum." (An Essay on the Periodical Discharge of the Human Female, by J. Power, M. D. 1832.) This hypothesis does not appear to have been formed from actual observations on the ovaria during menstruation, as Dr. Power has made no allusion to these in his work, and does not state that he has ever examined the body of any individual who died with the menses upon her. That an ovum, by which is usually meant an embryo enveloped in membranes, does not pass from the ovarium during menstruation, is evident from the fact that an ovum is never formed but as a consequence of impregnation, and that conception does not take place at the menstrual period. The facts which have now been related render it, however, extremely probable that all the phenomena of menstruation depend upon or are connected with some peculiar changes in the Graafian vesicles, in consequence of which an opening is formed in their peritoneal and proper coats. Whether an entire vesicle, or only the fluid it contains, escapes through this opening at the period of menstruation, further observations may hereafter determine. There is no proof whatever that an ovum passes along the fallopian tube into the uterus during menstruation, and it is not clearly established that this takes place even subsequent to conception.

[The opinion that menstruation is connected with periodical changes in the ovary is now embraced by most obstetrical physiologists, and especially by Négrier, Gendrin, and Raciborski. (See the author's *Human Physiology*, 5th edit. ii. 348: Philad. 1844.)]

Menstruation probably does not take place during infancy, because the ovaria are not then developed, and it is absent during pregnancy and lactation, because at these periods they are in a quiescent state. After the age of forty-six the catamenia cease, because the parenchymatous structure of the ovaria has partially disappeared, and the Graafian vesicles have degenerated into thick opaque cysts.

In many cases of disordered menstruation, chlorosis, and hysteria, which we have observed, the symptoms have been clearly referable to certain morbid states of the uterine appendages, and decided benefit has resulted from the application of those local remedies which were employed with the view of subduing the irritation, congestion, or inflammation, which appeared to be present in these parts of the uterine system.

II. Diseases of the Ovaria.

1. Inflammation and its consequences.—In the unimpregnated state, the ovaria are not very subject to those severe attacks of inflammation which produce an alteration in their structure. In most cases of puerperal fever, the peritoneal and parenchymatous textures of the ovaria become inflamed, and not unfrequently their structure becomes completely disorganized. In the article Puerperal Fever in this work, a full account has been given of these morbid changes,

and of the varied symptoms to which they give rise during life. The adhesions between the ovaria and fallopian tubes which are so frequently met with in examining the bodies of women of different ages and conditions of life, prove that slight attacks of inflammation of the peritoneal coat of the ovaria are not of rare occurrence, and that their presence is seldom discovered during life. Abscess of the ovarium from chronic inflammation of the parenchymatous structure, though a rare disease, does sometimes occur, as the following cases will show :

A woman, æt. 17, of the lowest and most unfortunate class of females, was a patient of Guy's Hospital, under the care of Dr. Bright, in the autumn of 1823. She was greatly emaciated, had a very quick and feeble pulse, a shining red tongue, and constant watchfulness. She suffered from constant and irresistible diarrhœa, and for many successive days vomited both food and medicine : the catamenia were absent. After having been in the hospital about two months, she suddenly complained of most acute pain over the abdomen, and in a few hours expired. On opening the abdomen, death appeared to have been produced by the effusion of a large quantity of pus into the peritoneal cavity, which escaped from an abscess in the right ovarium, which abscess appeared to arise from suppuration in the substance of the viscus, similar in every respect to phlegmonous abscess in any part of the body, and not connected with any cyst, or change or addition of structure, the product of morbid growth. (Dr. Seymour's Illustrations, p. 41.) A woman, whose case has been recorded by Dr. Taylor, of Philadelphia, had an abdominal tumour, which was considered to be an encysted dropsy of the ovary. On inspecting the body after death, the tumour, which occupied the whole abdominal cavity, and weighed seventeen pounds, was found to be formed by one of the ovaries, but in no respect did it resemble ovarian dropsy, being a large cyst, containing twenty pints of pus. (North American Med. and Surg. Journ., 1826.)

[When acute inflammation of the ovary is accompanied by metritis or peritonitis, it may be difficult, if not impracticable, to detect the ovarian phlegmasia. When the ovary is affected alone, burning pain will be experienced deep in the side of the pelvis in which it is situate, accompanied by the ordinary general symptoms that belong to acute inflammation of the internal viscera. Usually, however, the constitutional affection is not severe. Not much information can be obtained by examination *per vaginam*. A recent writer, however,(Leroy d'Etiolles,)speaks of having detected the ovarian tumour — owing to its sinking down—by the finger in the vagina. The finger, passed into the rectum, according to M. Löwenhardt, can reach the situation of the ovary, and may discover any tumefaction of the organ, or unusual tenderness on pressure. Pain is likewise experienced by the pressure of the distended rectum during defecation.

In the chronic form of ovaritis, the local phenomena are of the same character as in the acute, but less in degree, and it must be diagnosticated by the same mode of exploration. The disease is, however, necessarily more obscure.

Inflammation of the ovary, both acute and chronic, may terminate by resolution, by tumefaction and induration or softening, by suppuration, the formation of serous cysts, fibrous tumours, &c., and when both ovaries are affected, the menstrual function is interfered with, — generally, indeed, suspended. Sterility is a common consequence of the ovarian changes.

Ovaritis would seem to have been most frequently induced by sudden suppression of the catamenia, or by irregular exposure during the menstrual period. Most frequently, however, it follows labour, and has often been observed amongst the morbid appearances in puerperal fever. It has been affirmed, that females affected with gonorrhœa are liable to it, in the same manner as males, affected with the same disease, are liable to orchitis. Dr. Simpson, however, (Tweedie's *Library of Medicine*, 2d Amer. edit., iii. 342, Philad. 1842,) states, that he has watched diligently for its occurrence in some hundreds of cases of gonorrhœa, which have been under his care in the Lock Hospital of Edinburgh, but that he has only met with one, and that a doubtful instance. In two cases, recorded by M. Leroy d'Etiolles, the disease supervened on the use of uterine injections. The injections were sent with moderate force into the uterus by the aid of a gum-elastic tube. In one, the quantity of marsh mallows was ten drachms ; and in both cases, the liquid had scarcely reached the cavity of the uterus, before the patients complained of acute pain in the side.

The treatment differs in no respect from that which is adapted for inflammation of the uterus.]

2. **Cysts and Tumours of the Ovaria.** — There are perhaps no organs in the human body in which cysts containing a fluid are so frequently found developed as in the appendages of the uterus, and particularly in the ovaria. These sacs or cysts, which have not unfrequently been confounded with hydatids, constitute the disease termed encysted or ovarian dropsy ; and it scarcely admits of a doubt, from the progressive enlargement observed in the Graafian vesicles, that these cysts often originate in a morbid distension of these bodies. In other cases, ovarian dropsy arises from the development of a solitary serous cyst in the neighbourhood of the uterus, in the folds of the broad ligaments, or connected with the ovaria, if not imbedded in their substance. The whole substance of the ovarium is converted into a large bag containing a fluid, or into a congeries of cysts of different sizes, which have no communication with each other. These cysts, which differ considerably in the density of their coats, contain fluids which vary in colour and consistence. In some it is serous, mixed with a slimy, ropy fluid, like jelly ; in others it is a purulent fluid, or dark-coloured like coffee-grounds, and in two instances observed by us, the matter contained in these cysts resembled custard or soft cheese. A small ovarian cyst contained a thick dark-brown fluid like treacle, which did not become decomposed by pressure.

Dr. Hodgkin has recently investigated the structure and mode of formation of some of the more complicated varieties of ovarian cysts and tumours. He has given the following description of the

compound serous cyst, which is often complicated with malignant disease of the ovaria:

"In this form we observe on the interior surface of the principal cyst, elevations, more or less rounded and of various sizes, projecting into the interior of the cavity, and covered by a membrane which is continuous with the lining of the principal sac.

"On making an incision into these tumours, we find they also consist of cysts of a secondary order, filled by a secretion, often serous, but almost as frequently mucous. It is not, however, merely by this secretion that these cysts are filled. On looking more minutely into them, we shall generally find that from one or more points on the interior of these cysts there grows a cluster of other or lectiary cysts, upon which is reflected the lining membrane of the cyst in which they are contained. Cysts of the secondary order not unfrequently afford as complete specimens of a reflected serous membrane as either the pericardium or tunica vaginalis, the lining membrane of the containing cyst corresponding to the reflected portion, as that covering the contained bunch of cysts does to the close portion.

"The proportion which the contained cysts bear to the cavity of the membrane reflected over them is extremely various. Sometimes the fluid, especially when it is of a serous character, nearly fills the containing cyst, whilst the bunch of cysts is of very considerable size. At other times the superior cyst is almost entirely filled by those of the inferior order, in which case we may generally find that the nodulose or tuberose elevations, which we may have observed on the exterior of the containing cyst, are occasioned by the unequal development of the contained cysts; for those which have grown most rapidly and have attained the largest size, forcibly dilating that part of the cyst which is reflected over them, produce a kind of hernia at that part. It sometimes happens that the distension occasioned by the growth of the contained cysts is sufficient not only to disturb the even surface of the containing cyst, but actually to produce a rupture, which admits both of the escape of its fluid contents and of the unrepressed growth of the secondary or lectiary cysts, which took their origin from its internal surface." (Med. Chir. Trans. vol. xv. p. 282.)

Dr. Hodgkin endeavours to explain the formation of the different heterologe deposits or accidental structures on the same principles. Ovarian cysts are not unfrequently combined with a great enlargement of the organ, by which it becomes converted into a whitish, hard, cartilaginous mass, like the fibrous tumour of the uterus. These diseases are indeed not unfrequently present in the same individual, and they commence and run their course in the same manner. Portions of these fibrous tumours of the ovaria are sometimes converted into calcareous concretions like those of the uterus, or a process of softening commences in different parts, in consequence of which the fibrous structure is completely destroyed, and large irregular cavities are formed, containing a dark-coloured gelatinous fluid. Dr. Seymour in his valuable work has described ovarian tumours of the above description under the term scirrhus of the ovaria, though they are not of a malignant nature, and have no tendency to degenerate into cancer. "In the museum of the College of Physicians there is a preparation," Dr. Seymour observes, p. 59, "which has received the sanction of Dr. Baillie as a specimen of this rare disease. It is a section of a scirrhous ovarium, (resembling more a section of scirrhous testicle than the ordinary appearance of the ovarium under this disease,) which was in various parts beginning to soften, the substance breaking down into thick brown fetid fluid. This preparation was taken from a patient who died of cancer of the stomach, and Dr. Baillie says in his Catalogue is the same disease. It does not appear whether any distinguishing symptoms either of the locality of the disease or its peculiar nature existed during life."

The following example of this disease of the ovarium, which Dr. Seymour considers to be extremely rare, and the history of which he has recorded in his work, came under our notice several years ago.

At Blandford Mews on the 9th of August, 1828, we opened the body of a woman upwards of seventy years of age, who had died after long suffering from a tumour in the hypogastrium with ascites. An induration had been first perceived in the abdomen, between the navel and right ilium, nine years before, after she had suffered considerably for some months from sense of weight and dull pain in this situation. The size of the tumour gradually increased, and some years before death, (the belly being greatly distended with fluid,) the operation of paracentesis abdominis was performed by Mr. Blagden, and several pints of water were drawn off. In the course of the succeeding years the operation was frequently repeated; but the quantity of fluid evacuated gradually diminished, whilst the large indurated moveable mass came to occupy the whole of the lower part of the abdomen. She sank gradually from the interruption to the circulation caused by the tumour. On opening the abdomen, there was found attached to the fundus uteri, on the right side, an ovarian tumour weighing seven pounds, of a dense and fibrous structure. Several large cysts, containing a fluid varying in colour and consistence, adhered to the upper surface of the tumour. The peritoneum, in contact with its anterior surface, was converted into a cartilaginous substance, about a quarter of an inch in thickness. In the proper tissue of the uterus, at its fundus, was observed a fibro-cartilaginous tumour about the size of a large orange. In other respects the uterus was healthy.

The affections of the ovaria which have now been described do not partake of the nature of cancer, and have no disposition to degenerate into a malignant form. The injurious effects upon the system which they produce result entirely from the pressure and irritation which they excite in the abdominal and pelvic viscera, and some of the remote organs of the body. The cysts may descend between the bladder and rectum, and becoming firmly fixed by adhesions in this situation, interrupt the evacuation of the urine and fæces. In a case which lately came under our observation in the Saint Marylebone Infirmary, an ovarian cyst having become firmly impacted between the bladder and rectum, produced all the symptoms

of stricture of the rectum. In a lady now under our care, the presence of an ovarian or uterine tumour in the pelvis, which presses upon the neck of the bladder, renders it impossible for the bladder to be emptied without the introduction of the catheter. The effects of these tumours in impeding the progress of the child through the pelvis during labour have been fully described by Dr. Park and Dr. Merriman in the third and tenth volumes of the Medico-Chirurgical Transactions.

When the ovarian cysts remain at the brim of the pelvis, in the progress of their enlargement they gradually produce all the usual consequences of interrupted circulation in the pelvic viscera and lower extremities. Attacks of inflammation occasionally take place in their capsules, by which they contract adhesions with the surrounding organs, and pus is poured out into their cavities. After a time effusions of dropsical fluid take place into the peritoneal sac, and sooner or later the patient dies exhausted from the long-continued pressure and irritation of the abdominal and other viscera.

Encysted dropsy of the ovarium can generally be distinguished from ascites by the following symptoms. The tumour commences on one side of the abdomen, its surface is unequal, and its fluctuation, if felt at all, is very obscure. The health is at first but little impaired, and the thirst, scanty urine, and other symptoms which characterize general dropsy, are wanting. The catamenia are usually extremely irregular or altogether wanting. When both ovaria are diseased, Dr. Seymour states that the menses are always absent. Great difference is observed with respect to the progress of the disease in different individuals; in some it would appear to become stationary, or altogether cease to extend; while in others it goes on much more quickly to a fatal termination. In some cases, if we are to credit the histories which have been given by authors, recovery has taken place from a fright, blows, or from sudden exertion. Dr. Mead relates a case where eighteen pints of water escaped by a rupture of the sac through the umbilicus; Dr. Blundell relates that a lady afflicted with ovarian dropsy, falling from a carriage, struck her belly against a stone, and that a considerable discharge of urine occurred: she recovered, married, and dying subsequently of retroversion of the uterus, the cyst of her former complaint was found to have burst, and its contents effused into the abdominal cavity to have been absorbed.

Cysts containing a fatty matter intermixed with hair and teeth have frequently been met with either in the substance of one of the ovaria, or adhering to them by a narrow neck. They have been found before the age of puberty, and consequently do not arise from impregnation. In Ruysch's Museum was a tumour of teeth and hair which he found in a man's stomach. A little under the right kidney of a dead gelding, Mr. Colman met with a cyst containing fatty matter, hair, and teeth: and Mr. Brodie found a jaw, with full-grown teeth, in the bladder. Dr. Gordon met with a tumour in the thorax of a woman, which was considered during life to be aneurismal, but on examination after death appeared to be composed chiefly of the debris of a fœtus, which was situated in the anterior mediastinum, and adhered strongly to the sternum. It contained a sebaceous matter mixed with hairs, and a portion of a bone which appeared to be the superior maxillary bone. We are inclined to consider all these singular productions as wholly unconnected with conception in the bodies of the individuals in whom they have been found, and to view them as examples of that species of monstrosity which has been so fully described by Ollivier and Breschet, under the term *Diplogénèses par pénétration*.

Dr. Baillie states that the hairs are most of them loose in the fatty substance, but many of them also adhere to the inside of the capsule. Andral describes these hairs as sometimes intimately mixed up with the fatty matter, at other times as isolated from one another, or re-united into inextricable tufts. Their two extremities are usually alike, and in all the cases which he has examined there has been no bulb. (Précis d'Anatomie Pathologique, tom. iii. p. 710.)

Meckel, however, observed their bulbs in one of the cases which he examined, where the hairs were short and isolated, and were almost implanted into the walls of the sac which formed the envelopment of the tumour. He relates also from Tuniati, a case where the hairs had a white oval extremity covered by a fine skin, which was confined to the bulb, and was separated from it by an oleaginous fluid. (Memoire sur les poils et les dents, &c. par F. Meckel dans le Journal Complementaire cahier, 15 & 65.)

These hairs differ greatly in length and colour, some are only a few lines in length, some several inches; others have been seen which measured two feet three inches. Andral states that these hairs have not always a colour analogous to that of the hair of the individual in whom they are found. A negress had a cyst with cartilaginous walls in the mesentery. This contained a sebaceous matter, in the midst of which were numerous hairs, of a colour entirely different from the woolly black locks of the African woman. They were smooth, soft to the touch, white or red, and some of a silvery hue, like those of an infant of the European race.

In almost all the cases where teeth have been found, they have been implanted into the fragments of bony or cartilaginous matter, and have resembled the rudiments of maxillary bones and alveolæ. Meckel thinks that these accidental teeth are produced like ordinary teeth in capsules filled with a gelatinous fluid.

The presence of these tumours in the ovaria has sometimes given rise to serious obstacles to the delivery of the child in parturition, and to fatal inflammation after labour. The following example of this termination of the disease has been recorded by Dr. Seymour at page 8: "A woman about thirty years of age, some weeks after delivery, having been admitted into St. George's Hospital under the late Dr. Young with symptoms of enteritis, which speedily proved fatal, the inferior portion of the small intestines was found inflamed, which inflammation appeared to have been excited by the presence of a tumour of the size of a large cricket-ball, which had become attached by a narrow neck to the left ovarium. Its proper coat was of a fibrous texture and of a purple co

lour, and inclosed a mass of sebaceous matter, penetrated throughout with long fine hair; after removing which, a full-grown incisor tooth was found attached to the fibrous coat."

Treatment of Ovarian Cysts and Tumours.—Bloodletting, mercury, iodine, diuretics, emetics, long-continued friction or percussion, and a variety of other remedies have all been employed in encysted dropsy of the ovaria, and in most cases without the slightest benefit. Though the progress of the disease cannot be arrested by these means, yet the uneasy sensations produced by it admit of considerable alleviation. Inflammation of the cyst, and irritation of the bowels from its pressure, which often arise, may both be mitigated by the occasional application of leeches to the abdomen, by fomentations, and the use of cathartics and anodynes. When the distension becomes great, recourse must be had to the trocar, and by a repetition of the operation of tapping, the life of the patient may be prolonged, and considerable ease and comfort may be thus obtained, under a complaint which sooner or later must terminate unfavourably. On the practice of extirpating the ovaria when diseased, it is not necessary to offer any observations, as it has been abandoned by all who have made themselves acquainted with the pathology of these organs. Several years ago, an eminent accoucheur of this metropolis made an incision through the abdominal parietes of a young woman who had a movable tumour in the belly, which he considered to be ovarian, and which he thought it possible to extirpate, as Mr. Lizars had done in similar cases with success. On laying open the abdomen, a large fibro-cartilaginous tumour presented itself, which was attached to the fundus uteri by a thick peduncle. A ligature was applied round this, and the tumour cut off; but death soon followed in consequence of gangrene taking place in that portion of the bowel which had come in contact with the cut surface. The impossibility of distinguishing ovarian from uterine tumours, where the operation is wholly unjustifiable, was strikingly illustrated by this case.

[Subsequent experience has shown the justice of these remarks. Of late, many operations have been performed by Dr. Clay, Mr. Walne, Mr. Southam, Mr. J. Atlee, and others, and some of them successfully. They are confirmative of views long ably urged by Dr. Blundell, (*Researches, Physiological and Pathological*, Lond. 1828,) and strengthened by additional arguments which he lately furnished to the writer, (*Philadelphia Medical Examiner*, Jan. 27, 1844,) that incisions into the peritoneal sac are not necessarily so serious as has been generally imagined. Still, the difficulty in knowing the exact state of the parts is a formidable objection to the operation. (See Art. *Ovaires*, (Pathol.) in *Diet. de Méd.* xxii. 590; Paris, 1840; by Velpeau. *Edinb. Med. and Surg. Journal*, April, 1844, p. 467. *Brit. and For. Med. Review*, Oct. 1843, and Jan. 1844. *Amer. Journal of the Med. Sciences*, April, 1844, p. 456; and *Medical Examiner*, Aug. 24, 1844.)]

3. **Malignant Diseases of the Ovaria.**—Sometimes the ovarium is affected with encephaloid disease, or it is converted into a large irregular-shaped mass of cysts and tumours, the section of which presents all the characters of hematoid fungus. This fatal affection usually runs its course with great rapidity, and soon after its commencement the constitution of the patient is much more affected than in the organic diseases of the ovaria which have already been described.

M. Andral has accurately described the changes of structure produced in the ovaria by these malignant diseases. "Sometimes," he observes, "these masses are formed of fibrous, cartilaginous, or osseous tissue; in other cases they are almost entirely composed of encephaloid matter. The walls of the cysts are thick, and their cavities gradually enlarge until a tumour is formed, which fills not only the epigastrium, but the whole abdominal cavity. The outer surface of the tumour is unequal; in some points a fluctuation can be felt, while in others it has a hardness and density equal to bone." (*Andral*, Précis d'Anatomie Pathologique, tom. iii. p. 708.)

Dr. Seymour has also described this affection of the ovaria, and has pointed out the connection which often exists between it and cancerous and fungoid diseases in other parts of the body, as the pylorus, lymphatic glands, and even bony and muscular parts. This malignant disease, he remarks, may be recognised during life by the want of nutrition and broken health of the patient; the unevenness and rapid growth of the tumour, the simultaneous enlargement of glands in other parts of the body, and the occasional occurrence of lancinating pains in the part. The latter symptom is not constant. The pulse is quick and feeble, and as the disease proceeds there is hectic fever, and often aphthæ in the mouth, with an inexpressible sense of debility. (Diseases of the Ovaria, p. 61.)

This disease occurs even at an early period of life, and it appears to be excited in some instances by pregnancy, or to be called into activity by the process of impregnation. In the body of a young woman under twenty years of age, Dr. Carswell found on dissection an ovarian tumour of a malignant nature, as large as the gravid uterus at the full period. About five years ago we examined with Dr. Merriman and Mr. Prout the body of a woman about thirty years of age who had died from malignant disease of the right ovarium a few days after parturition. In the fourth month of pregnancy she began to suffer from a constant sense of uneasiness in the hypogastrium, irritability of stomach; the countenance became sallow, and the constitutional powers greatly reduced. The abdomen, not long after, began rapidly to enlarge, and before the end of the seventh month it had attained the size it usually acquires at the full period of pregnancy. An enormous cyst, which contained a dark-coloured gelatinous fluid, was found on dissection adhering to the right ovarium, and within this cyst were observed a number of tumours of different sizes and shades of colour, which when opened presented the true encephaloid or hematoid fungous character.

An interesting case of a similar description, in which the tumour at first offered an impediment to labour, and the performance of the Cæsarean operation was contemplated, has recently been recorded by Mr. Hewlett of Harrow, in the seven-

teenth volume of the Medical and Chirurgical Transactions.

Scrofulous and tubercular disease of the ovaria is very rarely met with. It is the least common of all the morbid alterations of structure to which the human ovaria are liable.

ROBERT LEE.

PALPITATION.—Palpitation may be defined to be an increase in either the force or the frequency of the heart's contractions, or of both, whereby they become not only sensible, but sometimes very troublesome to the patient. They may vary in force, from a scarcely perceptible degree to a violence which amounts to convulsion. Not unfrequently the sound of the beats is audible to the patient, especially when lying on his side; and in this position, the second as well as the first sound may occasionally be distinguished.

As palpitation is, under all circumstances, dependent on over-excitement of the nerves of the heart, the phenomenon is always essentially the same. The varieties which it presents arise merely from differences in the causes, and from the different routes which these causes pursue in order to arrive at, and convey their stimulus to the heart. Thus the blood conveys the stimulus *directly;* and this it does in three ways: first, by arriving in excess, as from violent exercise, plethora, &c.; secondly, by gorging the heart, in consequence of its transmission being impeded by a disease of the organ, or an obstacle in some other part of the circulation; thirdly, by being of too stimulant a nature, in consequence of the diet being exciting. The nerves, on the contrary, convey the stimulus to the cardiac plexus *indirectly*, as is the case in emotions of the mind, in dyspepsia, in hysteria, &c. The nerves and the blood may also convey the stimulus conjointly, as happens in fever, and in all other cases in which morbid nervous irritability co-exists with an organic affection, or a state of the blood leading to palpitation.

We have now to take a more particular view of palpitation in connection with its several causes; and we shall first glance at the causes of a physical or organic nature, and those dependent on states of the blood; and subsequently dwell at more length on nervous palpitation.

I. PALPITATION, CONNECTED WITH PHYSICAL CAUSES.—Of these causes, some are inherent in the heart itself, and others are exterior to it. The causes inherent in the heart fall under the following heads:—

1. Hypertrophy, and hypertrophy with dilatation. In these affections, palpitation consists in an increase both of the force and the frequency of the heart's action, the physical characters of the impulse and sounds being merely an exaggeration of those which the heart presents during a state of calm. (See HEART, HYPERTROPHY OF, and HEART, HYPERTROPHY WITH DILATATION OF.)

2. Dilatation with attenuation. Palpitation in this case consists in an increase of the frequency, but often not of the strength of the beats, though the patient may experience the *sensation* of an increased impulse. Palpitation of this kind is more obstinate than any other. Laennec cites an instance in which it lasted eight days; the pulse constantly beating 160 to 180 in the minute.

3. Disease of the valves. Palpitation from this cause varies in its characters according to the nature, situation, and extent of the valvular affection, and according to the presence or absence of hypertrophy, dilatation, or both. (See HEART, DISEASES OF THE VALVES OF THE.) Obstructions in the arterial system fall under this head.

4. Pericarditis, carditis, and inflammation of the internal membrane. In these, palpitation is either strong and bounding, or feeble, irregular, and unequal; differences which depend on circumstances explained in the articles on the above subjects.

5. Adhesion of the pericardium. Palpitation from this cause is violent, and of an abrupt, jogging, or tumbling character.

The physical causes of palpitation exterior to the heart are as follows:—

1. Acceleration of the circulation by muscular efforts. This is the most simple cause of palpitation, and it is strictly physiological. There is an increase both of the force and the frequency of the beats. Closely allied to this is the next: viz.—

2. Plethora. It gives rise to palpitation by preternaturally distending and stimulating the heart. The palpitation which sometimes exists during the first three or four months of pregnancy, is partly attributable to plethora, resulting from the suppressed catamenia, and partly to the nervous disturbance which attends so important a change in the system as that of utero-gestation.

3. Anæmia, whether from loss of blood, or from an insufficient quantity being made by the patient. In this case, the blood is always attenuated and impoverished, containing more serum and less fibrine than natural. Hence it moves with greater facility in the vessels, and probably, therefore, arrives at the heart either in redundant quantity or with morbid velocity, thus constituting a physical cause of palpitation. A highly irritable state of the nervous system generally accompanies anæmia, and is partly the cause of the palpitation. Hence we shall revert to this subject in treating of nervous palpitation.

4. Convulsive, epileptic, and hysteric fits. These cause palpitation, partly by occasioning too rapid a flow of blood to the heart, and partly by a participation of the organ itself in the spasmodic action.

5. Obesity. This causes palpitation in a threefold way: *a*, by the plethora with which it is usually accompanied; *b*, by the weight and inelasticity of the thoracic and abdominal parietes, whence the free expansion of the ribs and descent of the diaphragm are prevented; *c*, by the unusual resistance offered to the heart's propulsive action in consequence of the extended sphere of the circulation, and the pressure of the adipose tissue on the capillaries.

6. Obstructions in the lungs; namely, hydrothorax, empyema, pneumothorax, hepatization, extensive bronchitis, affecting the minute tubes, &c. These cause palpitation (so far as it is independent of a concomitant febrile movement) by obstructing the passage of blood through the lungs; whence the heart becomes gorged and preternaturally stimulated. Obstructions developed slowly, as tubercles, encephaloid tumours, aneurisms of the aorta, &c., commonly occasion little and sometimes no palpitation. For this there are

two reasons: 1st, that the mass of blood is diminished by the concomitant emaciation; 2dly, that supplementary respiration is established in the previous portions of lung, which not unfrequently become hypertrophous.

7. Asthmatic bronchial constriction. This causes palpitation by preventing the expansion of the lungs, and consequently impeding the circulation through them.

8. Acute laryngitis. According to our observation in a considerable number of cases, this affection causes palpitation in an eminent degree. We ascribe it to the same cause as in the preceding case, 7. In the last stage the palpitation ceases; for the engorgement of the heart becomes so excessive that the organ struggles and flutters rather than palpitates, and the patient, if not immediately relieved, speedily dies of asphyxia.

9. Abdominal infarction: namely, from enlarged liver or spleen, morbid growths, ascites, ovarian dropsy, advanced utero-gestation, &c. These occasion palpitation, principally by preventing the free descent of the diaphragm, and thus obstructing the circulation through the lungs, but partly also by compressing the aorta, and opposing the passage of the blood through it.

Amongst the causes of abdominal infarction is to be ranged tight-lacing. We were consulted by a military officer, who had brought on constant palpitation and slight hypertrophy by the habitual use of the dumb-bells while tightly girthed round the waist.

II. Palpitation from Causes operating purely through the Nervous System.—There are few affections which excite more alarm and anxiety in the mind of the patient than this. He fancies himself doomed to become a martyr to organic disease of the heart, of the horrors of which he has an exaggerated idea; and it is the more difficult to divest him of this impression, because the nervous state which gives rise to his complaint, imparts a fanciful, gloomy, and desponding tone to his imagination. Members of the medical profession are more apt than others to give way to these feelings; partly from their apprehensions being more keen, and partly from an impression too widely prevalent, that there is difficulty in distinguishing nervous from organic palpitation, and, consequently, that the patient must remain in a state of anxious uncertainty. It may be said for the consolation of such, that the diagnosis presents no difficulty, if to general signs is added a knowledge of those afforded by ausculation and percussion.

Nervous palpitation is dependent on dyspepsia, hypochondriasis, hysteria, chlorosis, gout, mental excitement, or a naturally irritable nervous temperament; and it presents different degrees, aspects, and habitudes, according as it depends on one or other of these causes. We shall describe its most common forms, and briefly advert to the connection between them and their causes.

1. The first and slightest degree is characterized by a tumbling or rolling motion of the heart, with a momentary feeling of fulness, tightness, and oppression. It is referable to an intermission of the heart's action, producing congestion; for the removal of which the succeeding beat is inordinately violent. This form occurs principally in dyspepsia, and it may result from so slight a degree of it, that the patient is not conscious of being an invalid. Slight acidity or flatulence, for instance, is sufficient for its production.

Dyspeptics do not in general experience a more aggravated form of palpitation, unless they are of a nervous temperament.

2. In the next degree there is a series of quick, weak, fluttering, irregular beats, with slight anxiety, acceleration of the respiration, and a quivering sensation in the epigastrium: this may last from a few minutes to half an hour or an hour, and occur only at distant and irregular intervals, or several times a day, especially when the patient is startled. It is apt to supervene at bed-time, keeping the patient wakeful and restless during a considerable part of the night.

This form presents itself in nervous and hypochondriacal dyspepsia, in hysteria, and in individuals who, either from disease or mental excitement, have fallen into a state of high nervous irritability. Amongst the latter class are to be ranked literary and scientific men, and hard students in general. This form occasionally, though rarely, occurs without any other apparent origin than a very slight degree of indigestion, the patient being otherwise strong and healthy.

Individuals, especially females, with naturally small or thin hearts,—a class characterized by a delicate frame and a languid, feeble circulation, are predisposed to the variety of palpitation under consideration.

3. The next degree amounts to perfect palpitation, consisting in increased impulse, sound and frequency of the beats, sometimes accompanied with irregularity of action, and generally with more or less anxiety, dyspnœa, and even orthopnœa. The attack may be only occasional, or may occur several times a day, or may even last with little intermission for several days together. This form is rare in pure dyspepsia, but is of common occurrence in dyspepsia complicated with hypochondriasis, or engrafted on a nervous temperament. It manifests itself principally, however, in hysterical subjects, and those remarkable for great nervous mobility and irritability. In a lady of the latter class we have seen it exist in an exquisite degree, being excited by the slightest causes. A word, a look, an idea, a movement, the most frugal meal, the most gentle stimulant, even a glass of water, sufficed to induce a violent fit, attended with heat and flushing; and she frequently passed a great part of the night in a state of the most distressing orthopnœa. The heart and lungs were sound, and she was restored to health by bitters, tonics, cold bathing, sea air, and a nutritious but unstimulating diet.

There are many individuals without any definite ailment, yet calling themselves *delicate* or *not strong*, who, after a full meal, after any unusual fatigue, or any extraordinary mental excitement, become languid, listless, restless, sometimes drowsy, with heat, acceleration of the pulse and respiration, and a more or less extensive arterial throbbing. This is generally connected with slight palpitation; so slight, indeed, that the patient is seldom conscious of it. The symptoms usually subside after a little repose, especially a tranquil sleep.

Sometimes a slight degree of palpitation subsists

without intermission for years, especially in young persons of a constitution at once plethoric and nervous, and more particularly in females about the period of puberty.

We above adverted to palpitation from anæmia, whether occasioned by loss of blood or by defective sanguification. In this the blood is always in a thin and impoverished condition, from a deficiency of fibrine and an excess of serum, and the nervous system is generally in a highly irritable state. The variety is highly important, as it comprises a great number of cases, and requires a peculiar mode of treatment.

When the palpitation results from loss of blood, the phenomenon is denominated *reaction*. If the hemorrhage has been restricted to a brief period, as a few hours or days, the patient soon recovers; but if it has been protracted, as is often the case from piles, chronic dysentery, menorrhagia, polypus, or cancer of the uterus, &c. the case is much more obstinate and intractable; for not only is the state of anæmia fully established, in consequence of the system being reduced to a condition which renders it incapable of reproducing good blood; but, by the impoverished state of the fluids, a train of nervous symptoms is engendered, which greatly exasperates the malady. Under these circumstances we have repeatedly seen palpitation last almost without intermission for many weeks and even months, but gradually yield to tonic medicines, diet, and regimen.

Anæmia arising simply from defective sanguification, as in chlorosis, of the male as well as the female, places the patient in circumstances very similar to those last described; and the palpitation is of the nature above noticed as the third degree. Here, also, we have seen it last, with little intermission, for several weeks and even months. In a medical gentleman, the heart bounded violently 120 to 150 times per minute for upwards of four months. Bleeding exasperated the affection, and the blood drawn was very serous, and so deficient in fibrine as scarcely to form a coagulum.

This state of the blood, in connection with palpitation and arterial throbbing, constitutes, in our opinion, an important feature in the pathology of purpura hemorrhagica; for in several well characterized cases which we have seen, and in others which have been communicated to us, the conditions alluded to existed in an eminent degree.

Nervous palpitation may give rise to hypertrophy, (see Hypertrophy, *exciting causes*;) but it is surprising how long the heart will in most cases resist this affection; and when the palpitation is subdued, how soon it will recover itself after undergoing slight enlargement. According to our observation it rarely requires less than a year, and sometimes several, of very constant palpitation, to produce confirmed hypertrophy.

Every variety of nervous palpitation may be attended with arterial throbbing; and the throbbing may be either universal, or limited to a particular part, even to individual arteries, especially the aorta and carotids. Hence, nervous palpitation is, in general, more audible to the patient than *organic*, the sound appearing to rush through his ears, especially when he reposes on his side in bed, since each arterial throb causes a rustling movement of his pillow.

The contraction of the heart in nervous palpitation is less remarkable for force than for an abrupt, bounding, and jerking character, and on this the arterial throbbing is mainly dependent; since the vessels receive the jerk communicated to the blood by the impulse of the heart. (Treatise on Diseases of the Heart, by Dr. Hope, page 74 to 78.)

Diagnosis of Nervous Palpitation. 1. *General Signs.* — Nervous palpitation may be discriminated from organic by the presence of some or all of the following signs, viz. by its not being excited, but, on the contrary, relieved by corporeal exercise of such a nature as would certainly disturb the action of a diseased heart; by its disposition to supervene while the patient is at rest, especially at the commencement of the night when he lies wakeful in bed; by a fluttering in the epigastrium; by the general prevalence of nervous symptoms; by the affection being aggravated when the nervous symptoms undergo an exacerbation; by the pulse and the action of the heart being natural during the intervals between the attacks; and by the intervals being long when the general health is good. Nervous palpitation, in short, is *intermittent*, its causes being only occasional; whereas organic palpitation deserves the epithet of *continued*, its causes being constant.

To the above category of diagnostic signs, some add, as characteristic of nervous palpitation, an increase of it after meals, or when the stomach is loaded or deranged, and an amelioration produced by dyspeptic remedies; but as the stomach produces the same effects when there is disease of the heart, these signs are not pathognomonic of nervous palpitation. To this point we would particularly direct the attention of practitioners; because many, in forming their diagnosis of the affections in question, regard the dyspeptic signs as paramount in value to all others.

Though nervous palpitation is often attended with various familiar nervous affections of the head, as pain, or sensations of heat or cold confined to particular parts and coming and going suddenly, temporary vertigo, tinnitus, and confusion of the sight, not increased by lying down or stooping; it is not, when purely nervous, accompanied with genuine signs of cerebral determination or congestion: there is no universal throbbing headach, with weight and tension, increased by stooping or the recumbent position; no stunning sounds and pains in the head on suddenly lying down or rising up; no permanent somnolency, apoplectic stupor, or regular apoplectic fits, as in hypertrophy, &c.

2. *Physical Signs.*—"In nervous palpitation," says Laennec, "the first impression which the application of the stethoscope to the region of the heart produces on the ear, shows at once that this organ has not great dimensions. The sound, although clear, is not loud over a great extent; and the shock, even when it at first appears strong, has little real impulsive force, for it does not sensibly elevate the head of the observer. This last sign appears to me the most important and the most certain of all, when we add to it the *frequency* of the pulsations, which is always greater than in the natural state. Most commonly it is from eighty-four to ninety-six per minute." This is a

very accurate description of nervous action of the heart. The impulse is analogous to that which occurs in reaction from loss of blood, and which we have elsewhere denominated *jerking*. It may be added that, in nervous palpitation, though the sounds are increased, they are not materially altered in quality, the first sound being, as in the healthy state, longer and more suppressed than the second.

The physical signs of nervous palpitation will be rendered more apparent by being contrasted with those of organic. We shall, therefore, summarily recapitulate the latter.

In *dilatation*, dullness on percussion over an increased extent indicates that the organ is enlarged; further evidence of which is derived from the dullness, and the impulse being situated lower down than natural. The first sound is short, smart, and clear, resembling, and in dilatation with attenuation becoming identical with, the second. Both sounds are louder than in a greater degree of nervous palpitation.

In *hypertrophy with dilatation*, the dulness on percussion is increased over a still greater extent, and the dulness and impulse are also lower down than natural. Both sounds are very loud, and the first is shortened, though less so than in pure dilatation. The impulse is a smart, violent blow, possessing much more force than in nervous palpitation, and very frequently raising the head of the auscultator.

In *simple hypertrophy*, the impulse is a slow, gradual, and powerful heaving, very sensibly elevating the head. Both sounds are diminished, and in extreme cases almost suppressed. These characters are so different from those of nervous palpitation, that it is only by inattention that the two affections can be confounded.

In *disease of the valves* there is a *permanent* bellows, sawing, or rasping murmur; whereas murmur in nervous palpitation is only occasional, and of a soft character. If the valvular contraction be great, the action of the heart is irregular. Irregularity also occurs in nervous palpitation, but it is not accompanied by those symptoms of an embarrassed circulation which invariably attend valvular disease, and in too palpable a form to be mistaken. Should hypertrophy, dilatation, or both, coexist with valvular disease, their signs, as above described, will likewise be present.

The pulse in nervous palpitation is materially different from that in organic disease. In the former it is jerking, but has little fulness, strength, and incompressibility. In dilatation it is full and soft; in hypertrophy with dilatation, it is full, strong, and sustained; and in simple hypertrophy, though less full, it is strong, sustained, and even hard. In valvular disease it presents different characters according to the situation and degree of the lesion, (see VALVES, DISEASES OF, *general signs*,) but the presence of other signs of the valvular affection will enable the practitioner to distinguish the pulse from that of nervous palpitation.

To the physical signs of nervous palpitation, may, in many instances, be added an intermittent bellows and sawing murmur of the heart and sometimes of the arteries, which we have elsewhere attributed to the morbid velocity with which the blood is propelled by the sudden and as it were spasmodic contraction of the heart. (Treatise on the Diseases of the Heart, by Dr. Hope, p. 76,) The murmur occurs whenever the action of the organ is excited; and in some instances the slightest causes suffice to produce the effect, as a momentary mental emotion, a change of posture, (from the recumbent to the erect for instance,) a constrained position, a meal, flatus in the stomach, &c. We have often found the phenomenon to subsist for a few seconds or minutes only, that is, so long as the exciting cause continued in operation. The patient, if asked whether he is conscious of palpitation, replies in the affirmative; yet the pulse may not be strong—it may even be small and weak; but it will be sharp or jerking. It is the velocity, therefore, and not the power of the heart's contraction which causes the murmur.

III. PALPITATION FROM PHYSICAL AND NERVOUS CAUSES.—Nothing is more common than a conjunction of nervous with organic affections of the heart; and these are the cases which present the greatest difficulty in diagnosis, as the one masks the other, and it is not easy for the inexperienced practitioner to assign to each the share which it holds in the production of the symptoms. He will best qualify himself for this task by acquiring a sound knowledge of the two classes of affections separately. Hence it is unnecessary to enlarge on this subject. We have elsewhere given cases illustrating the combination. (Treatise, &c. p. 493.)

Treatment of Palpitation.—Palpitation being only a symptom, the treatment must be mainly directed to the primary affections. To advert to it here in all its details would be a superfluous repetition, as it is discussed at large in the several articles devoted to the primary affections. Palpitation from organic disease of the heart is so intimately connected with the disease itself, that abstract observations on treatment would convey no definite information; and we therefore refer the reader wholly to the various articles on that subject—to which he will find a guide in the general article, HEART, DISEASES OF THE. The treatment for nervous pulsation of the aorta is noticed at the conclusion of the article AORTA, ANEURISM OF THE. In the articles HYSTERIA, CHLOROSIS, and especially INDIGESTION, he will find ample information on the subjects to which they respectively refer. Here, therefore, we shall merely direct our attention to a few points, which, though embraced in a general plan of treatment for the primary affection, are not discussed with so specific a reference to palpitation as the practitioner might probably wish.

1. *Palpitation from Plethora.*—This is to be treated in the first instance by a free use of the lancet, and by two or three calomel and colocynth purges at bed-time, worked off by a draught consisting of equal parts of infus. gentian. and infus. sennæ c. with tinct. sennæ ʒi. and potassæ tartrat. ʒi. ad ii. or any other purgative neutral salt. This draught should be repeated every morning for a week or ten days, until the force of the palpitation has in a great measure subsided. The subsequent part of the treatment is principally of a prophylactic nature, the indication being to prevent the regeneration of too much and too rich blood. The patient should abstain from animal food on alternate days, and should always take it in limited

quantity. His diet should consist principally of farinaceous articles and vegetables, and his beverage should be toast and water. As few things are more conducive to plethora than an excessive indulgence in sleep, he would do well to restrict himself, for a time at least, to six or seven hours in the twenty-four, or even less. While the palpitation exists, it is dangerous to take violent corporeal exercise, as hypertrophy might be induced; but when the symptom seems to be provoked by exertion, an active life is eminently serviceable. We have thought it necessary to insist on the present subject, as we have found plethora to be a frequent cause of hypertrophy, especially in those who, while plethoric and subject to palpitation, are compelled by their position in society to lead a laborious life. Such is the case with a large class of female servants in the country. The luxurious and indolent, when plethoric, suffer in a scarcely less degree.

2. *Palpitation during early utero-gestation.*—Should this be evidently connected with plethora, it will readily yield to a moderate abstraction of blood, a few gentle saline aperients, a spare, unstimulating diet, and a cool air with good ventilation.

3. *Dyspeptic palpitation.*—As the palpitation generally supervenes at the moment when there is a morbid stimulus in the stomach, whether this result from ill-digested food, as is usually the case in atonic dyspepsia, or from the irritation of almost any ingesta in the inflammatory species, it is evident that a judicious regulation of the diet will constitute one of the most important features in the treatment. To the article INDIGESTION the reader has already been referred. He will there find an able account of the medical treatment adapted to all the circumstances of the complaint. So long as palpitation exists in connection with symptoms obviously demanding the exhibition of medicines, as, for instance, inflammatory irritation of the mucous membrane, complete torpor of all the alimentary functions, and with various others, it is vain to expect a cessation of the palpitation until these symptoms have been relieved. But palpitation not unfrequently remains after all urgent symptoms have been removed, and the patient scarcely looks upon himself in the light of an invalid. Often have we seen it form the most delicate test of the slightest dietetic indiscretion. Here, then, it is that diet and regimen are of the first importance: they must complete what medicine began.

They are to be adapted to the nature of each case, and to vary with the variations of its circumstances. In *atonic* gastric dyspepsia the patient should follow the rules judiciously laid down in INDIGESTION, ii. p. 619 et seq.

At p. 620 is also an excellent account of the means to be employed in order to restore the harmonious action of the bowels with the stomach, of restoring or increasing the activity of the excretory organs, and of restoring the tone or improving the innervation of the stomach. Under the latter head the subjects of mineral waters, bathing, friction, clothing, are fully discussed.

In *inflammatory* gastric dyspepsia, not only the medical, but the dietetic and regiminal treatment is very different. Both will be found in the same article, p. 627, so ably laid down as to supersede the necessity for further remark.

4. *Palpitation from anæmia.*—When this results from a sudden loss of blood in a healthy individual, little more is requisite for its cure than patience, as the symptom subsides in proportion as blood of the natural consistence is regenerated, which takes place in the course of ten days or a fortnight, and sometimes considerably earlier.

When the anæmia results from protracted or repeated hemorrhage, or from inadequate sanguification, as in chlorotic females, persevering medical treatment is in general necessary. The palpitation, and its usual concomitants, headach and arterial throbbing, are invariably exasperated by further detraction of blood, to which some resort from a mistaken view of the nature and cause of the headach. More and richer blood must be made, and the remedies best calculated to effect this object are the preparations of iron, with aloes; the latter being useful not only as a bitter tonic, but by its aperient operation to counteract the too stimulant effect of the chalybeate. We have seldom been disappointed by the pills of Dr. Abercrombie, consisting of two grains of sulphate of iron, two of aloes, and five of the compound cinnamon powder in two pills, taken at dinner, and, if necessary, at bed-time also, the quantity of aloes being diminished if it should act more than once, or gently twice a day. Should these pills create nausea, as sometimes happens, an excellent substitute is to be found in the decoct. aloes comp. f.℥ss ad f.℥i (just sufficient to move the bowels gently once a day) at bed-time, with a drachm of the vinum ferri thrice a day.

The carbonate of iron in doses of from one to three drachms thrice a day, and two grains of the pil. aloes cum myrr. and pil. galbani comp. respectively at bed-time, is likewise an efficacious plan of treatment. Under the use of all these remedies we have seen patients speedily recover from the most unpromising circumstances. The remedies are to be assisted by a nutritious animal diet, much fresh air and gentle exercise, and by the use of the flesh-brush, salt-water sponging, and even shower-bath.

Before the medicines begin to take effect, the patient is often importunate for some palliative to relieve the urgency of the palpitation. We have found this object best effected by the hydrocyanic acid (*m* i. ad vi.); the acetate of morphia (gr. 1-3); or by the following draught: tinct. hyoscyami ℥ss, sp. ætheris nitrici ℥ss, mist. camph. ℥x. syrupi aurant. ℥i. Fiat haustus. Each remedy may be administered once, twice, or thrice a day, according to the necessity.

5. *Nervous palpitation.*—Individuals in whom palpitation is referable to a highly irritable nervous temperament, cannot, in general, bear the stimulus of chalybeates in the first instance, though they eventually prove of the greatest advantage. With such, it is best to commence with the lightest bitters, and pass progressively to bark and mineral acids, and thence to metallic tonics. Of these sulphate of zinc is one of the least stimulant, and a grain, with extract of gentian, in a pill twice or thrice a day, will often agree as well even as bitters. In the cases in question, however, medicines are of far less importance, in the first instance,

than regiminal tonics: viz. a bracing air by the sea-side, sea-bathing, the shower-bath, or salt-water friction, a regular, nutritious, but unstimulating diet, and a tranquil cheerful mind. After preliminary measures of this kind for a few weeks, chalybeates, especially in the form of mineral waters, will in general prove singularly beneficial.

J. Hope.

[Not unfrequently, cases of irregularity of the heart's action, especially of the rhythm, are met with, which appear to be greatly dependent upon a want of nervous power generally, and of the nerves distributed to the heart in particular. These cases are often the source of great anxiety to the patient. Auscultation may exhibit no evidence of valvular derangement or of altered nutrition of the organ; but a loss of beat is observed occasionally at the wrist, whilst, at the same time, the impulse of the heart may be exaggerated. This pathological condition is often accompanied by languor, and by irregularity of calorification,—the hands and feet being kept warm with difficulty; and, occasionally, immediately after the irregularity of the heart's action is felt in the epigastrium, the patient breaks out into a profuse perspiration. Along with these phenomena he is affected with flatulence of the stomach and bowels, and, in many cases, the anomalous symptoms are present, which have been referred to as belonging to Torpor of the Colon (q. v.). The subjects of these cases are often gouty.

The treatment ought to consist of agents that are calculated to obviate debility and impressibility. The preparations of iron—as the citrate—in full doses are of great service; and a glass or two of wine at dinner, or of ale or porter, with animal food in due quantity, has afforded marked relief.

PALSY, BELL'S. See Paralysis.

PALSY, SHAKING. See Paralysis.]

PANCREAS, DISEASES OF THE.—By the ancient writers on medicine, the use and the importance of the pancreas were, it is to be presumed, little thought of; for the venerable father of our art has not even named an organ concerning whose office such a variety of opinions were advanced in after ages. Of these opinions a short yet lucid account has been given by De Graaf. (Tractatus Anatomico-Medicus de Succi Pancreatici Natura et Usu, cap. 2.) Up to the period when the pancreatic duct was discovered by Wirsangus, the notion most generally adopted seems to have been this,—that the office of the pancreas was to afford support to the vessels, and to serve as a cushion or bolster to the stomach, to protect the latter, when in a state of repletion, from being pressed and injured by the vertebræ.* In latter times, however, it has been clearly ascertained to be an important gland. Its office, we now know, is to secrete a fluid analogous to the saliva, (hence it has, by Haller and other eminent physiologists, been called a salivary gland,) and to transmit by its excretory duct that fluid to the duodenum. The pancreatic juice, mixing with the bile, probably renders it more bland; and by the agency of the pancreatico-bilious fluid, combined with the lymph of the intestines, the food, already converted into chyme in the stomach, is further changed and becomes chyle, the pabulum of the blood, which has emphatically been termed *the life*.

It is worthy of remark that many eminent persons who were ignorant of the true physiology of the pancreas, who were unacquainted with the existence of its peculiar secretion, yet considered it to be the secret source of a variety of important maladies. Thus Schenkius says that the pancreas and mesentery are the seats of innumerable and wonderful diseases; (Exercit. Anatom. lib. i. sect. 2, cap. xxi.) and Fernelius (Lib. vi. pathol. c. 7,) treating of the morbid affections of the same parts, affirms that in them he has generally observed the causes of diarrhœa, dysentery, cachexia, atrophy, languor, slow fevers, &c. Riolanus again supposes the pancreas to be the obscure seat of intermittents, of hypochondriasis, and of other chronic disorders.

Important, however, as the office of this gland is known to be at the present day, we cannot ascribe to it an influence so extensive and so powerful as these old and most respectable writers were disposed to assign to it, at a period when its functions were very imperfectly or not at all understood. The morbid conditions to which the pancreas is subject are in fact not numerous. Dr. Baillie remarks that it is upon the whole less liable to disease than any other important gland in the body. (See his posthumous volume, p. 207.) The symptoms of its disease are moreover obscure, being for the most part such as belong equally to morbid affections of other parts contained within the abdominal cavity. It is, indeed, very seldom that we are able to discover pancreatic disease in the living subject, and rarely do we find, upon examination after death, that this gland has been the only or even the principal seat of disease.

[There is reason to believe that a close relation and intimate sympathy exist between the salivary glands proper, and the abdominal salivary gland or pancreas; and it would seem that there is a sympathy between the testes and pancreas (See art. Parotitis; and Dr. F. Battersby, in Dublin Journal of Med. Science, May, 1844, p. 238). It is, on the average, about six or seven inches long, and weighs from two and a half to three or four ounces. Of six observed cases, the mean weight, according to Professor Gross (*Elements of Pathological Anatomy*, ii. 357, Boston, 1839,) was two and a half ounces, and the mean length seven inches.]

The deviations of the pancreas from the healthy state have been regarded by several authors of high reputation as either of very small moment, or as far too obscure to be recognised with any tolerable degree of precision. Of all those whose Genera Morborum are comprised in Cullen's Synopsis, Vogel alone says one word about the pancreas, and he barely notices its inflammation—adding the words, 'notæ deficiunt.' In the comprehensive and valuable work of Dr. Mason Good, we meet with nothing respecting the diseases of the gland in question. Yet though the opinion of Dr. Baillie above referred to may be

* Such was the notion of the celebrated Vesalius.

perfectly correct, and though reading and experience may have forced upon us the conviction that the diseases to which the pancreas is liable can hardly be ascertained during life, or, at all events, cannot be ascertained until they have proceeded too far to receive any substantial benefit from medicine, still, in a work like the present, the morbid affections of so important a part must not be passed over in silence. We proceed, therefore, to offer such an account of those morbid affections as the perusal of some of the best authors, conjoined with our own (it must be confessed very limited) observations, enables us to supply.

Inflammation of the pancreas is a disease of rare occurrence, at least it has seldom been described by morbid anatomists. A recent instance, however, of what would appear to have been true inflammation of the gland, has been given in the Medico-Chirurgical Transactions, (vol. xvi. part 2,) upon the high authority of Mr. Lawrence. In the case to which we refer, the pancreas was throughout of a dull red colour, which contrasted very remarkably with the bloodless condition of other parts. It was externally firm to the touch, and upon being cut into felt very firm and crisp; but after having been left for eight-and-forty hours it became soft. Mr. Lawrence does not seem to regard this hardness as a morbid condition of the gland, and for the following reasons:—1st, because persons in whom such a state of the pancreas has been observed have died of other diseases, without a symptom of morbid affection of this particular part having developed itself during life: 2dly, because in these cases the structure of the gland has been in every respect perfectly healthy; and 3dly, because the hardness soon disappears after death. With all respect, however, for the opinion of so experienced a morbid anatomist and so acute an observer as Mr. Lawrence, we cannot altogether coincide with him in his reasoning upon this point—we do not feel satisfied that the induration in question is not a morbid state. The pancreas is by no means the only important organ which may be seriously diseased, and yet during the life of the patient betray no symptom of such disease, and the individual die at last of some other malady. Induration of other organs may be discovered upon dissection—such induration as has been always deemed to be unequivocally morbid—yet it shall disappear not many hours after death. Such we have known to be the case as regards the liver. We have met with at least one example of enormously hypertrophied and indurated liver, where the induration was lost a few hours after its removal from the body. Mr. Lawrence's strongest argument is the otherwise healthy condition of the pancreas; but Mr. Baillie, while he remarks that hardness of this gland is accompanied with little appearance to the eye of its structure being altered, proceeds to observe that he believes this hardness to be the beginning of a process by which the pancreas becomes truly scirrhous. "It very seldom," he says, "in this state shows, in any part, the real scirrhous structure, but I have seen this to be the case, which renders it very probable that the one is the beginning of a change into the other." (See Morbid Anatomy.)

More frequently than with inflammation of the pancreas do we meet with what are usually regarded as its consequences. Examples of **abscess** and **ulceration** are to be met with in various authors. In the writings of Tulpius, and Bartholinus,* and Guido Patin, as cited by Dr. Abercrombie, (Pathological and Practical Researches, &c. Pathology of the Pancreas,) an immense abscess was found occupying the whole of the gland. Portal relates several instances of this disease, and one especially deserves notice, in which the pancreas was found in a complete state of suppuration, in a man who died suddenly after two or three attacks of vomiting followed by syncope: he had previously been suffering under a paroxysm of gout from which he was supposed to be recovering. (Portal, vol. v. p. 551 et seq.) Another case has been recorded by Dr. Percival. Dr. Baillie never saw but one case of pancreatic abscess, and that case did not occur in his own practice, but was under the care of the present Dr. Heberden.

Gangrene of the pancreas has been mentioned by Bonetus, Portal, and others.

Remarkable instances of **scirrhus of the pancreas** are also on record. Riolanus found the gland in such a state, and equalling the liver in size, in the person of Augustine Thuanus. Morgagni (Epist. xxx. 10) relates a case where the pancreas was of unusual magnitude, and universally unequal with round tubercles of considerable size, and itself of almost cartilaginous hardness. Similar examples may be found briefly related by Dr. Abercombie. (See his work above cited.) Several cases have also occurred to the writer of the present article in which the pancreas *seemed* to be preternaturally hard; but he has met with but one instance where the gland was decidedly and greatly indurated, almost as hard as cartilage. The subject was a young married lady, who, after having for many years suffered from intense pain of head, died with immense effusion in the ventricles of the brain. The abdomen was examined in consequence of her having, a short time previous to her death, complained of excessive pain in the epigastric region. No morbid appearance was discovered, excepting the extraordinary induration of pancreas above mentioned.

Cancer of the pancreas has sometimes been noticed. De Graaf (Tractatus, &c. cap. vii. See also Bonetus, de vomitu observ. 55) has a striking case from the Miscellanea Curiosa, Med.-Phys. Germanorum. It occurred in the person of a surgeon. The pancreas, which had perforated the diaphragm, was two spans long, and two hands in breadth; it was decayed and putrid—an ulcerated mass, resembling cancer. In this case not only was the diaphragm perforated, but the spine was eroded, and the vena cava had given way. The cancerous mass had spread further, and had contaminated both kidneys, rendering them putrid and excessively black.

We are not aware of the existence of a symptom or set of symptoms by which inflammation of the pancreas can be ascertained in the living sub-

* See also Fabricius (Wm.) cent. 4, obs. 71. Antest Program. to the treatise of Fernelius, "de abditis rerum causis"—De Graaf 'de Succo Pancreatico,' cap. vii. case cited from Highmore.

ject, nor are those which attend ulceration or scirrhus of that gland by any means well defined. The pancreas, says Dr. Pemberton, (Diseases of Abdominal Viscera,) is endowed with so small a degree of sensibility that ulceration is found after death, when no pain or other symptom had previously existed which could lead to a suspicion that inflammation was going on. If, however, there be a sense of weight or deep-seated pain in the region of the stomach, or referred to the back, with vomiting* of ingesta and of watery fluid; if there be gnawing pain at the boundaries of the thorax and abdomen, urgent thirst, and emaciation,† and yet no perceptible tumour in the hypochondria, nor other symptom, in addition to those just mentioned, to mark an original disease of the stomach, or concave surface of the liver, or of the gall-bladder or ducts, or of the small intestines, or, we may add, of the kidneys, we may safely conclude that the seat of disease is the pancreas.

When disease has so far advanced that the emaciation is extreme, the indurated gland may be distinctly felt: by placing one hand upon the back and the other upon the stomach, and employing considerable pressure, an expression of pain deep-seated under the hand will in all probability be elicited from the patient.

But, besides the diseases already mentioned, the pancreas is subject to certain other morbid affections. Thus, while tubercle of the gland is mentioned by Morgagni, (Epist. xxxiii. art. 28,) a case of tuberculated sarcoma is related in the Medico-Chirurgical Transactions, (vol. ix. part ii. p. 342;) Dr. Abercrombie has given several instances of a mixed state of disease—of hypertrophy, with partial induration and partial softening, resembling medullary sarcoma. (Pathological and Practical Researches.) "Many cases," says the latter author, "are on record, of chronic disease of the pancreas, exhibiting the same diversity of symptoms which occurred in the examples now described, and nearly in the following proportion. Of twenty-seven cases, which I find mentioned by various writers, six were fatal with gradual wasting and obscure dyspeptic symptoms, without any urgent symptoms; in eight there was frequent vomiting, with more or less pain in the epigastric region; and thirteen were fatal with long-continued pain, without vomiting. In some of these the pain extended to the back, and in others it was much increased by taking food. In several there were dropsical symptoms, and in three or four there was jaundice from the tumour compressing the biliary ducts. In the morbid appearances, also, there was great variety."

Calculous concretions have been found in the pancreas. Instances of this have been given by De Graaf, Portal, Baillie, &c. The calculi in Dr. Baillie's case were found to consist of carbonate of lime. (See Baillie's Morbid Anatomy; Pemberton on Disease of Abdominal Viscera; Abercrombie.)

The pancreas, it is said, has been entirely wanting; but we doubt the fact: we believe that in the cases adduced some portion of the gland existed. The entire pancreas, as Haller observes, cannot be removed without the duodenum.‡

After what has been said respecting diseases of the pancreas, of the great obscurity of their symptoms, &c., it cannot be expected that any thing very satisfactory can be proposed as to their treatment. To use the words of Dr. Pemberton, "the remedies for a diseased pancreas are as imperfect as the symptoms which mark its derangement." Could we even be assured that the pancreas is the primary or the principal seat of disease, we should still perhaps be at a loss how to meet the mischief by strictly appropriate remedies, and as, in the present state of our knowledge, we never can decidedly pronounce that the gland in question is the chief seat of disease, our practice must necessarily be vague; it must necessarily be directed to symptoms which belong equally to morbid affections of other organs as well as to those of the pancreas. Pain we must attempt to relieve by leeches, or cupping, or blisters. We must endeavour to restrain the efforts to vomit, and we must secure at least one regular evacuation daily. Of the remedies calculated to allay the irritable condition of the stomach which accompanies disease of the pancreas, a great variety might be mentioned: we select the following, simple indeed, but often very useful:—first, a drachm of tincture of senna with five minims of laudanum, to be taken a quarter of an hour before each meal;§ secondly, pulv. calumb. et pulv. rhei āā gr. v., sodæ subcarb. gr. v., pulv. capsici gr. ss., in any convenient vehicle just before dinner; or gr. v. of the compound rhubarb pill may enable the stomach to retain a portion, at least, of the food, which would otherwise be rejected altogether. Of the other numerous remedies which are commonly employed in derangement of stomach, we need say nothing in this place. They may each prove occasionally useful, but they more generally fail even to palliate the symptoms when the pancreas is in fault.

The bowels may be regulated by mild laxatives. The plan of certain old practitioners is not to be despised. When they met with cases in which pain of stomach or of some neighbouring viscus was chiefly complained of, yet no good evidence existed of actual disease of any particular part, they gave an opiate draught at bed-time, and a common laxative in the morning. This practice was, we believe, at least as useful as any of the more scientific plans which have been adopted in later times. The patients probably lived as long and their days were as comfortable as they have been under modern treatment.

In one word, respecting diseases of the pan-

* The diseased pancreas may in various ways occasion vomiting; by irritating the contiguous stomach by its hardness or roughness, or by pressing upon it by its preternatural size; or it may compress the duodenum. Or the vomiting may be caused by the secretion of the gland being vitiated by its being deficient, or altogether suppressed. It is said that dogs, whose pancreas has been removed, have died of bilious vomiting.

† There is an observation of Prosper Alpinus which we must not pass over in silence. Speaking of inflammation of the omentum, mesentery, and *pancreas*, he says, "Necessario prædictarum partium insensibilium phlegmone oppressi in expirando angustiam sentiunt."—*De Medicinâ Methodicâ*, lib. vii.

‡ Utilitatem magnam (pancreatis scilicet) perpetuitas suadet, quâ pancreas in plerisque animalibus reperitur; *neque refutant pauca experimenta, in robusto animali facta, quod particula pancreatis extirpatæ vitale superfuit, totum enim pancreas auferri nequit, nisi cum duodeno.*—Haller Primæ Lineæ Physiologiæ.

§ In the distressing nausea and vomiting attendant upon the early stage of pregnancy, the above is a very excellent remedy.

creas, we think that, in their earlier stages, when they cannot be exactly ascertained, our practice must be in a great degree empirical; when they have reached that point that they can be pretty accurately ascertained, little or nothing can be effected, nothing probably in the way of cure, little by way of arresting the progress of the disease. Still, however, it is our duty to recommend an alterative course of medicine; at any rate we may palliate the more distressing symptoms; we may, as in various other hopeless maladies, render the closing days of our patients comparatively comfortable.

[Various diseases have been ascribed to an increased secretion, or hypercrinia of the fluid of the pancreas,—cases of enterorrhœa, for example; and it was suggested by M. Dupuytren, whether the pancreas may not furnish the matter evacuated by persons labouring under cholera. It has, moreover, been presumed by M. Mondière, (*Recherches sur l'Histoire Pathologique du Pancréas*, in *Archiv. Général.*, Mai et Juillet, 1836,) that the fluid of pyrosis may proceed from the pancreas; and, as remarked elsewhere, (*Practice of Medicine*, 2d edit. i. 581, Philad. 1844,) we cannot say that these speculations are altogether devoid of foundation, or that they are irrational; but it may be averred with safety, that the observed phenomena and arguments in their favour are by no means convincing. (See on the Diseases of the Pancreas, Art. *Pancréas*, (Path.) in Dict. de Médecine, xxiii. 68, Paris, 1841.)]

H. W. Carter.

PARALYSIS, from παράλυσις, *debilitas*, *resolutio nervorum* of Celsus.

At an early period of the history of medicine it was a surmise of Galen that two different states or degrees of nervous influence were requisite to supply sensibility and the motive power to any part of the body; but it was reserved to the present century to enlarge upon this idea, and by careful induction from facts disclosed by minute anatomical investigation, from the results of direct experiment and from the effects of certain pathological conditions, to infer that parts endowed with sensation and voluntary motion are provided with two classes of nerves, the one *sentient*, the other *motive* nerves.

If a part be deprived of the influence of one or both of these classes of nerves, from whatever cause, and to a greater or less degree and extent, that part is reduced to the condition indicated by the term *paralysis*, which we accordingly define as the total loss or diminution of sensation or motion, or of both.

Arctæus was the first of the ancients to employ the word paralysis to any extent, but he limits its signification to denote merely a loss of the power of motion, (κίνησιος μοῦνον ἐνεργείης τέ πάρεσις.) The term occurs only once in the writings of Hippocrates, and then in a letter to Perdiccas—de structurâ hominis. By him, and by many writers after him, apoplexy and paralysis were confounded together, and even by Heberden they have been considered as only different degrees of the same disease.

It is with much justice that Rostan has reprobated the custom of considering the condition of paralysis as a disease in itself, when it undoubtedly should be regarded as a phenomenon belonging to and dependent on a number of different affections; and it is much to be questioned whether such a species as that given by Rachoux, (Dict. de Médecine, Art. Paralysie,) viz. *idiopathic paralysis*, is at all admissible.

From the definition above given, it is obvious that those parts which are naturally endowed with sensation and the power of motion can alone be deemed susceptible of the paralytic state. We cannot, therefore, apply the term to that condition of a secreting organ when it is incapable of performing its function, as some writers have done when they speak of paralysis of the kidney, liver, or pancreas, &c.

From the definition we may further infer a primary division of paralysis into that of *sensation*, or *anæsthesia* (ἀναισθήσιη), and that of *motion* (ἀκινήσια), each of which may vary in degree, and may be therefore *complete* or *incomplete*.

[Paralysis of Sensation.]—Although the term *anæsthesia* seems to have originally been applied by Arctæus to denote absence or defect of the sense of touch, there is no reason, from the etymology of the word, why it should not be more extensively applied to signify absence or defect of sensation in general. Adopting this broader signification, then, we place under this head those affections of the senses which are denominated *amaurosis*, *anosmia*, *cophosis* or *dysæcia*, *ageustia*, as the sight, smell, hearing, or taste, may be severally deficient, and finally paralysis of the sense of touch, which is specially denominated by some *anæsthesia*.

For full details respecting **Amaurosis** we refer to the article under that head. (See Amaurosis.)

Anosmia (loss of smell), rarely exists as a solitary complaint, except it be occasioned, as we believe it generally is, by an abuse of sternutatories. It is sometimes a congenital defect, an instance of which is mentioned by Dr. Good, in the person of a young lady. Another instance is known to the writer, in the case of a gentleman, now past the age of fifty.

Tumours compressing the olfactory nerves, organic alterations of their roots, acute affections, or long-continued irritation of the Schneiderian membrane, polypi, disease of the spongy or other bones of the nose, external injuries, may be enumerated as the principal causes of anosmia. Serres alludes to several cases of disease of the roots of the olfactory nerves affecting the sense of smell, and seems to think that alteration of the external root exerts a more powerful influence than that of either of the others.

The cure of this affection is accomplished by the removal of the above-mentioned causes, and is attainable only so far as that object can be effected.

Cophosis (*deafness*) is not an uncommon symptom in fevers, or in acute diseases in which there is disposition to head affection. Disease or compression of the auditory nerve—disease of the petrous bone—obliteration of some of the canals or passages connected with the auditory apparatus—otitis—are among its most usual causes. There are likewise cases of nervous deafness, as Mr

Saunders designates it, dependent on constitutional causes, producing temporary derangement of the functions of the auditory nerve.

If the deafness depend on obstruction, it is of course submitted to surgical treatment; but if it be merely a functional derangement, topical counter-irritation and a general tonic treatment have been generally found successful in the early stage.

Ageustia (*loss of taste*) sometimes accompanies local palsy of the tongue or of the face, and sometimes is produced mechanically by the deposit which covers the sentient surface of the tongue in fevers, exanthemata, &c., preventing the application of the sapid substances to the nervous extremities. It is likewise occasioned, as Dr. Good observes, by the long-continued use of tobacco, whether by smoking or chewing, or of other acrid narcotics. In the Boston Medical and Surgical Journal for May, 1832, Dr. Robbins relates the case of a lady in whom the sense of taste on one side of the tongue was impaired by want of exercise. Owing to the presence of a very painful but not unsound tooth on the left side, the whole force of mastication was thrown upon the teeth of the right side. Liquids were from habit successfully passed through the mouth without coming in contact with the left side. After two years' continuance in this state, the painful tooth was extracted, and when the immediate effects of the operation of extraction had subsided, the lady observed that her sense of taste on the left side was considerably impaired in acuteness, and that she failed to perceive the true flavour of whatever was presented to its action. (Vide Lond. Med. Gazette, vol. x. p. 175.)

This affection, like the preceding, is to be cured by the removal of its exciting cause.

Anæsthesia (*diminution or absence of the sense of touch or of feeling*) affords much matter of interest to the pathological inquirer. We meet with it most commonly as a precursor of paralysis of motion, either in a minor degree, a condition of numbness, or in that of total insensibility; frequently it accompanies paralysis of motion, and rarely follows it.* It more frequently precedes paralysis of motion of the lower than of the upper limbs. Sometimes it is coexistent with paralysis of motion of the opposite side, as in a case by Cullen, of a gentleman who had loss of motion without loss of sense of one arm, and loss of sense with perfect motion of the other. (See, also, Ephem. Natur. Curios., cent. ii. obs. 196.)

Several cases of *complete* loss of feeling are now on record. In these cases the patients are insensible to injuries of the severest kind,—wounds with sharp instruments, burns, &c., and are constantly liable to accidents of this description, the skin having lost its protecting sensibility. Dr. Good quotes a case in which the anæsthesia had its seat in the right arm; in this case, the occurrence of a phlegmon on the affected arm excited no uneasiness, and some time after, when the patient accidentally fractured his arm, he received intimation of the accident merely from the crash which it produced. Dr. Yellowley gives the instance of a man who put his feet into boiling water, and was not aware of the height of the temperature till he perceived a vesication forming on one of his legs: in a similar case by Mr. Earle, the high temperature of some hot grains, into which the patient put his legs, was first evinced by the formation of large sloughs. We may add that in Dr. Yellowley's case above alluded to, a knife was introduced deep beneath the nail of the thumb without occasioning pain or uneasiness.

When anæsthesia occupies the external integument, in the immediate neighbourhood of any of the orifices at which that membrane becomes continuous with the mucous membranes, the latter are generally similarly affected to a greater or less extent. Thus in the cases of partial loss of feeling of the face, the conjunctiva of the eye, so acutely sensitive in its healthy condition, can bear pressure or friction, or even pricking with the point of a sharp instrument. The eyeball having thus lost its proper sensibility, the cornea is apt to become inflamed, opaque, ulcerated, and finally destruction of the eye ensues. Hence some physiologists have, with but little show of reason, argued that the nerve supplying sensibility to the conjunctiva is likewise the nerve of sight. The mucous membranes of the nose and mouth likewise participate in the insensibility in these cases. In the nose, the membrane is unaffected by pungent substances, as ammonia, &c., although the sense of smell is perfect: the introduction of a feather into the nostril does not produce any of the usual effects. In the mouth there is equal insensibility of the mucous membrane of the gums, lips, and tongue; the individual will bear even mustard in the mouth without being incommoded: he is insensible of the presence of food in that part of his mouth which is the seat of the disease; so much so that, in a patient in this condition, a portion of food has been known to remain in the mouth till it became putrid. In these cases the sense of taste is generally affected. Mr. Broughton (Med. and Phys. Journ. 1827) has related an interesting case, in which the anæsthesia succeeded to the recovery of paralysis of motion of the lower extremities; it occupied the skin of the nates, part of the loins, perineum, penis, and upper part of the thighs. In this case the insensibility extended to a great portion of the genito-urinary mucous membrane; the patient was unconscious of the presence of a catheter in the urethra; erections of the penis and emission of the semen took place likewise without the patient being sensible of them. But the most remarkable and interesting phenomenon connected with the case, was the kind of incontinence of urine which was present: "when the bladder was full, the urine overflowed on the slightest irregular movement, and ran out of the penis unconsciously to the patient." A similar case is detailed by Ollivier, in which incontinence of urine was coexistent with anæsthesia of the inner and anterior part of the thighs, and of the penis and scrotum. In these instances we presume that the insensibility of the inner membrane of the bladder is sufficient to account for the incontinence of urine, for how can those muscular fibres, which to a certain extent perform the office of a sphincter to the neck of the bladder, be stimulated to contrac-

* In a case reported by Dr. Colles, of Dublin, in the Appendix to Sir C. Bell's work, loss of feeling followed the cure of a partial paralysis of motion of the face.

tion, unless the mucous membrane of that viscus be sensible of the presence of the urine?

Anæsthesia is most frequently partial in its extent; we sometimes meet with persons who possess from birth a numbness of one or more fingers. Often the affection begins locally, but increases its extent gradually. Cases are recorded in which the anæsthesia was universal; in others it has been reported to occupy the whole surface, with the exception of a small portion, as in a case by Ollivier, where a patch on the right hip was the only sensible spot on the whole cutaneous surface; and in another quoted by Andral, in which the insensibility extended over the whole body, excepting a small round spot on one of the cheeks.

In partial anæsthesia existing on one side of the body, we generally find the insensibility limited with the utmost precision by the median line. These cases vary in extent from half the body to an extremity, part of an extremity, part of the face, &c. It has also been known to occur in numerous round spots, eight or ten in number, the surrounding skin being perfectly natural. (Andral's Lecture, Lancet, No. 497.) In the anæsthesia of the face we may here mention an invariable consequence; the patient complains that when he puts a glass or cup to his lips, it conveys to him the sensation of its margin being broken; and this circumstance is often the first to direct his attention to the complaint. When there is cutaneous anæsthesia of the extremities, we generally find that the power over the voluntary muscles is impaired; and this we might, *à priori*, expect to follow loss of sensation. A case by Dr. Yellowley confirms this supposition. The patient used to drop glasses, plates, &c. if her attention were directed from them; but so long as she kept her eyes on them, she held them in perfect safety. A precisely similar instance is adduced by Foville, (Dict. de Méd. et Chirurg. art. *Encephale*) in proof of the above assertion, as related to him by Sir A. Cooper. A third case we may mention from Dr. Ley. (Appendix to Bell on the Nerves, No. lxxxv.) There was defective sensibility on one side of the body; the patient could hold her child in the arm of that side so long as her attention was directed to it; but if surrounding objects withdrew her from the notice of the state of her arm, the flexors gradually relaxed, and the child was in hazard of falling. The fact is further illustrated by an incident of daily occurrence. When a person, from sitting in an awkward position, produces numbness in his lower extremity by the prolonged pressure on the sciatic nerve, he will find it almost impossible to stand on the benumbed leg alone, and that from the absence of the consciousness that the foot is applied to the ground.

Anæsthesia varies in its modes of access. In some cases the patient's attention is first attracted by the sensation of fine sand intervening between the skin and the object touched: in others there is a feeling compared to the creeping of insects over the skin, and thence named *formication*: both these after a little merge into total insensibility. Often the anæsthesia appears suddenly and without any premonitory symptom.

We cannot always assign a satisfactory cause for the condition which we have been describing. In general, however, it is referable to some change influencing the nerves which supply sensibility to the affected part or parts; in the trunk and extremities, the sensific filaments of the spinal nerves; in the face, the ganglionic portion of the fifth pair. This alteration may exist either in the nervous trunks themselves, or in the nervous centres, where the nerves are connected with them. Thus pressure, wound, or disease of a nerve, is constantly known to affect the sensibility of the parts supplied by it. Several instances are to be found in authors where anæsthesia followed concussion of the spinal marrow; injury or disease of the posterior bundles of the same could produce a like result. Loss of sensibility is often connected, too, with cerebral disease. Local injuries of various kinds will produce anæsthesia; it sometimes has commenced from a cicatrix, or succeeded the application of a blister. The sudden or continued exposure to cold is not an unfrequent cause: most of the cases related by Mr. Broughton were plainly attributable to this cause. Mr. Swan gives a case in which anæsthesia of the hand was produced by a violent pressure applied to the wrist; and Roche mentions one, in which the insensibility occupied the integument over the trajet of a ball which entered the body on the right side and ran round beneath the skin till it struck against one of the lumbar vertebræ.

Anæsthesia is likewise often connected with hysteria and hypochondriasis; sometimes it follows parturition, as in the case above quoted from Dr. Ley: it is also sometimes coexistent with mental derangement. We may add, that the condition of the circulation in a limb exerts a marked influence on its sensibility; suspended or retarded circulation removing or diminishing the sense of feeling, as is matter of daily observation.

The duration of anæsthesia is uncertain and variable: sometimes the sensibility will return when least expected; at other times it will resist all treatment. When it is the result of spinal concussion, it may be removed by the treatment generally adopted for that accident; and when produced by cold, the prognosis may also be favourable.

The treatment of this condition is founded more on experiment than on a correct pathology. It chiefly consists in local applications to the affected parts. Friction with various stimulants; baths of different descriptions, warm or cold; douches, blisters, or epispastics of other forms; electricity; may be enumerated as the chief curative agents. If an organic cause exist, either in one of the nervous centres, or in a trunk of a nerve, it is hardly necessary to observe that primary attention should be directed to ascertain how far that is removable.

We may here briefly allude to the remarkable epidemic which appeared in Paris in the summer and autumn of 1828. The most singular and constant symptom was a numbness, passing into a total insensibility of the skin and subcutaneous tissues on the hands and feet, and sometimes on other parts, of more or less extent. This was in general preceded by some symptoms of gastric or intestinal irritation, which continued often for many days or weeks. The insensibility, which was in general preceded by formication or prick

ing pains, was uniformly accompanied with an œdematous state of the affected limb; vesications, likewise, formed on it in different places: the skin was sometimes red, sometimes of a dark colour, and the epidermis detached in some places. The insensibility was so great in many cases, that no pain was experienced when pins were passed into the skin. In some cases there was subsultus tendinum; in others the muscles were paralysed; yet according to the report of M. Genest, (Archives Gen. de Méd. Oct. 1828,) from whom we have taken the above statement, the latter condition was not very frequent; but from the statement of Chomel to the Academy (sitting of 26th of August), it appears that considerable weakness of the feet and hands, with impossibility to move them, was a symptom very constant.

No organic lesion of the nervous system could be detected sufficient to account for this remarkable epidemic. From the examinations detailed by Genest, the intestinal mucous membrane seems to have been the seat of several ulcerations. To us there appears much analogy between this epidemic and that which is met with in tropical climates, the beriberi, or the more chronic barbiers.

Paralysis of Motion.—The second form of paralysis is that of motion, to which, from its being of so frequent occurrence and so serious in its effects, the term *paralysis* is more especially applied.

Like that of sensation, paralysis of motion is either complete or incomplete. It presents some variety in its mode of invasion: it may come on instantaneously, and without any premonitory symptom; the affected parts becoming suddenly flaccid and powerless, and thrown into a state of complete resolution: at other times the paralysis is preceded by inordinate muscular action, viz. by spasms attended with a considerable degree of pain, the muscles sometimes remaining in a state of rigidity after the invasion of the paralysis. Lastly, we find paralysis coming on slowly and gradually; the part being at first affected as to its sensibility, then becoming slightly torpid, and at length paralysed; the palsy then spreads on step by step, till it occupies a considerable extent. This is the form to which the term *creeping* palsy has been applied.

There are certain phenomena which constantly succeed to the attack of palsy. Wasting of a limb is an almost invariable consequence of paralysis. This would appear to arise more especially from the atrophy of the muscles, the result of prolonged inactivity; and, in part, from the deranged nutrition, in consequence of the removal of due nervous power. The muscles of a limb, when in a state of complete resolution for any long period, lose their colour, and are diminished in firmness as well as in dimensions; the colouring matter in some cases is completely absorbed, and a yellowish tissue, which however still retains the fibrous and fasciculated character, replaces the original muscle; a change which by some has been described as the conversion of muscle into fat.

The circulation in palsied limbs is said to be more languid than in healthy ones, and the pulsations of the arteries have been stated to be diminished in force and even in frequency. These statements, however, do not appear to have been founded on facts universally or even extensively observed, to say nothing of the sources of fallacy which lie in the way of a conclusive comparison of the relative force of arterial pulsations.

The nerves of palsied limbs do not in general present any obvious change. They have, however, been found increased in size, and of a yellowish colour; but it should be noticed that the enlargement might have arisen from the thickening of the neurilemma, or from the infiltration of a fluid, and not from any increase of the medullary substance. We may, moreover, state as the result of the experience of Andral, that he has never found the nerves of paralytic limbs either atrophied or hypertrophied. (Andral's Pathol. Anat. by Townsend, vol. ii. p. 797.) Sir C. Bell, however, is of opinion, as Dr. Cooke says, that the nerves of palsied limbs do lose some of their substance. When the nerves of a paralysed limb are diseased, it has been remarked that the wasting is more rapid and more manifest than in the ordinary cases, (see article Atrophy;) and judging from our own observation, we would infer that the atrophy is likewise more rapid when the paralysis is the result of spinal than when caused by cerebral disease. Thus how much more frequently do we observe wasting of the limbs of paraplegics than of those in whom the paralysis is in the form of hemiplegia! Yet we have seen limbs in the state of palsy, and that of some duration, in which there could not be detected any difference from sound limbs. We not unfrequently meet with palsied limbs in an œdematous state, more especially in old persons; we may also remark that the state of paralysis favours the formation of vesifications on the affected parts,—an occurrence more commonly noticed in paraplegia.

Much has been written respecting the temperature of paralytic limbs. Does it differ from that of healthy ones? or are they, from the want of nervous power or any other cause, less able to resist the influence of cold? Mr. Earle, by actual thermometric examination of a considerable number of paralysed limbs, found that their temperature was some degrees lower than that of the sound ones, and observes that, wherever nervous energy is impaired, the part loses the power of maintaining a healthy standard temperature, because the integrity of the nervous power is essential to the complete performance of the calorific function. (Med. Chir. Trans. vol. vii.) Observation, however, has frequently shown that paralytic limbs may be of a higher temperature than others. Dr. Abercrombie's views on this head place the question in so clear a point of view, that we shall transcribe his remarks: "In regard to the temperature of paralytic limbs, I think it is generally supposed that they are colder than the healthy limbs; but this does not appear to be the case. The truth seems to be that they have lost in some degree that remarkable power possessed by the living body, in a healthy state, of preserving a medium temperature, and that, *according to the temperature to which they have been exposed*, paralytic parts become hotter or colder than sound parts which have been exposed to the same tem-

perature. A case has been related to me by a friend in which a medical man, paying a visit to a paralytic patient, found the paralytic arm so intensely hot that it was painful to touch it. This, upon inquiry, was found to be owing to the application of very hot bran, which the patient had made to the arm by the advice of a neighbour, though he was himself insensible to the change of temperature." (Abercrombie on the Brain, &c. p. 288.)

The sensibility of paralysed limbs is generally more or less impaired; most frequently there is paralysis of sensation incomplete or complete, the latter, however, being very rare. Dr. Cooke states that he "never saw a case of palsy in which sensation was entirely lost; and an eminent physician of great experience asserts that a total loss of feeling in this disease is very rare." Sometimes the sensibility is exalted, and the patient can hardly endure the slightest touch upon the affected limb. Dr. Abercrombie refers to a case in which the sensibility of the arm was so increased, that the least breath of cold air excited convulsion. The sensibility may likewise be so altered that the patient will draw erroneous inferences from his sense of touch; thus, cold bodies will feel hot to him, and as in the case related by Dr. Falconer, (Mem. Med. Soc. Lond. vol. vii.) the feeling of heat will subside as the body in contact gradually acquires the temperature of the limb.

In general there is but little pain in palsied limbs; Drs. Cooke and Abercrombie, however, speak of patients who suffered extreme pain. We have observed pain accompanying incomplete palsy, and we should say that it is in such cases that pain is to be expected, there being in general a more or less spasmodic condition of the muscles.

The vital and natural functions, says Cooke, are generally but little affected in palsy; sometimes those of respiration and circulation are somewhat impeded, but this is generally towards the close of the patient's life. The bowels are usually more torpid, and less easily brought under the influence of purgative medicines, but the excretions are not diminished. When the paralysis extends to the sphincter, and to the muscular coat of the bladder, the involuntary discharges are apt to lead one to imagine that the excretions are increased in quantity.

Paralytics are in general irritable and peevish, and, if the palsy be of long duration, sometimes become quite imbecile. Dr. Cooke relates a case, however, in which the attack of paralysis produced a remarkable change in the temper of the patient;—"from being of an irascible and irritable disposition, he became perfectly placid, and remained so until his death about two years after." The powers of the mind too are not unfrequently affected, as well antecedently as subsequently to the attack of paralysis. The memory is most frequently affected in these cases: the power of recollecting names, whether of persons or things, as well as the memory of languages, is often lost; the habit of substituting one name for another, and a predilection for particular names, which the patient will apply to all persons and on all occasions, are also among the deranged mental phenomena attendant on these cases. In some instances, paralytics even invent names which are unintelligible to all except those who are in daily attendance on them. The writer remembers the case of an old domestic, rather famous for loquaciousness when in health, in whom some curious defects of verbal memory preceded for a considerable period the paralytic attack which ended her days. She entirely forgot the names of persons, and first lost the recollection of the names of those with whom she was most familiar; yet for some she invented names, which seemed to please her better than the real names of the individuals, as she almost invariably rejected the real names when they were mentioned to her. She had nearly the same defect as to names of things; she often pronounced the first syllable of the name of any thing she wished to ask for, but could get no farther; nor would she be put right. She at length grew irritable and suspicious of even those who ministered to her wants; she husbanded her few articles of property with the greatest care and closest watchfulness; and ultimately she became amaurotic, and the subject of extensive palsy. Such instances are, we believe, by no means rare. Dr. Bright relates one in some respects similar.

Causes of Paralysis.—It is to the effect of some alteration in the centres or ultimate ramifications of the cerebro-spinal system that observation has taught us to look for the true cause of most of the paralytic affections met with in practice. There are forms of palsy where no appreciable alteration can be detected in any part of the nervous system. Such are those in which the palsy arises from the impregnation with metallic particles — lead, mercury, and others, for which no satisfactory cause is assignable. Yet even in these cases we are scarcely warranted in denying the existence of organic lesions merely because they are not obvious to our senses. We would here observe that close and unbiassed observation is more called for to promote the elucidation of the class of affections we are now considering than of any other, and we may add that an accurate symptomatology is as essential to this important end as an exact and minute detection of the several morbid appearances of the cerebro-spinal system. It is mainly by a series of pathological facts, well arranged, that we can hope to unravel with certainty the many intricacies connected with that system in its healthy as well as its morbid state. To accumulated experimental and pathological investigations we owe in a great measure the advances made within latter years, and to such we look forward, and not without sanguine hope, for a still farther insight into a class of diseases at once dreadful to the afflicted and perplexing to the practitioner.

Paralysis is said to occur more frequently in men than in women, and generally in persons past the meridian of life; it is a common disorder of old age. Those of a sanguine and what has been called nervous diathesis are most liable to it.

Its exciting causes are such as dispose the brain, spinal marrow, or nerves to diseased action acute or chronic; accidents, and a variety of other causes, both moral and physical. (See Apoplexy and Inflammation of the Brain.) Exposure

to the action of particles of mercury, lead, and arsenic, produces a peculiar form of paralysis, the paralysis *venenata* of Cullen.

Paralysis is often co-existent with various nervous diseases — hysteria, epilepsy, mania, hypochondriasis. It also sometimes appears after parturition, and occasionally with phlegmasia dolens.

The duration of paralysis depends so much on its cause, the constitution of the patient, and various other circumstances, that no general statement can be made regarding it.

With respect to the extent of parts affected, we find that paralysis has, to use the words of Heberden, innumerable degrees, from the torpor and debility of a single joint of a finger to a complete apoplexy, in which sense and motion vanish from the body. It may, therefore, be divided into, 1. general paralysis, 2. partial paralysis.

I. General Paralysis. — When both sides of the body are paralysed, and when, in fact, the whole muscular system is deprived of the power of motion, so that the patient cannot move in any way by an effort of his own, the condition is that of general paralysis. If the four extremities be paralysed, the affection would likewise come under this head. It sometimes happens, that one or more of the senses are impaired in addition to the motive power; and not unfrequently the general sensibility of the body is diminished or destroyed.

It is remarkable to what an extent paralysis of motion as well as sensation will affect the body without destroying life. Some interesting cases are recorded in which the palsy was so general as completely to deprive the patient of all means of communication with the surrounding world. One of the most remarkable of these is that related by M. Defermon, in the Bulletin des Sciences Médicales for January 1828. It is defective, however, inasmuch as the examination of the body was not permitted. M. C. I., of a nervous habit, and having lived a dissipated life, was suddenly seized with amaurosis; which being suspected to have had a syphilitic origin, was treated accordingly, without success. Immediately afterwards there came on a remarkable exaltation of all the other senses, but especially of that of touch. His intellect being perfect, he was enabled to continue in the duties of his office in an important financial department. Some years afterwards his hearing became dull, and gradually advanced to total deafness; at length general paralysis of sense and motion, except in the tongue and muscles of deglutition and respiration, supervened; the whole body became insensible, and the limbs were successively paralysed, without the least trace of external lesion.

The patient was thus shut out from all means of communication with others; yet his speech and intellects were unimpaired. It was accidentally discovered that a small patch on the right cheek retained its sensibility; and by tracing letters on this sensible spot, his wife and children were enabled to maintain an intercourse of ideas with him! After some time, however, his strength began to fail, the paralysis extended to the sphincters, and he sank.

Another somewhat similar but more complete case is recorded in the Edinburgh Medical and Surgical Journal, for 1828, by Mr. Davies Gilbert, the late distinguished President of the Royal Society.

The young girl, the subject of it, had been born a little before her full time, and at birth was in a state of great weakness. She did not manifest in any way the instinct which usually directs other infants to seek their natural nourishment; she was consequently reared with much difficulty. One of her eyes was much smaller than the other, which seemed to be of the natural size. Some weeks after birth she was seized with violent convulsions, which lasted some time. She continued, however, to grow like other children, but a deficiency of sensation and motion became daily more obvious. She was destitute of the sense of sight and hearing, and a cataract was observed upon the eye which was of natural dimensions. The sense of taste appeared to be tolerably perfect, as she afforded some feeble sign of satisfaction when sweetmeats were given to her. As to voluntary motions they were totally defective, and she arrived at her seventeenth year without having ever raised her head, carried her hand to her mouth, or put a foot to the ground. She was quite dumb, and only occasionally uttered a feeble cry, which her attendants regarded as indicating a desire for food. Some time before death, her feebleness seemed to increase, and on the day in which she completed her seventeenth year she expired, so tranquilly that she was supposed to have fallen asleep. It is positively stated that this girl had shown some appearances of menstruation, as well as other signs of puberty.

On dissection, the brain appeared perfectly healthy, but on raising it from the cranium it was found that the dura mater lining the basis cranii was deficient, and its place occupied by a thin and semi-transparent membrane, very loose and singularly arranged; the tentorium cerebelli was likewise deficient, so that the posterior lobe of the brain rested immediately upon the upper surface of the cerebellum. All the nerves were perfectly regular.

General paralysis is most commonly the result of apoplexy, and is then accompanied with stertor, coma, and the other symptoms usually attendant on that disease. The continuance of circulation and respiration are the only remaining signs of life, the power of swallowing is impaired or lost, and the excretions pass involuntarily. This condition either gradually increases,—the paralysis extending to the muscles of respiration, and the vital powers becoming slowly exhausted,—or the coma subsides, consciousness is restored, and the patient is found paralysed in sensation and motion, to a greater or less extent; or the paralysis may totally disappear with returning consciousness.

Paralysis from apoplexy is easily detected, by the suddenness of its invasion and other concomitant circumstances. (See Apoplexy.) In surgical practice, this condition of general palsy is met with not unfrequently as a consequence of a severe concussion or compression of the brain.

We observe other cases of general paralysis, characterized by a development more or less slow. The tardy progress of these cases distinguishes them sufficiently from those which are the result of apoplexy. Most of them partake of the nature

of that described above as *creeping palsy;* there is some variety as to the part first affected: sometimes the eyelids fall, or a hand, or foot, or even a finger or toe become paralysed; sometimes, also, the tongue: at other times an impaired condition or complete loss of sensibility precedes the paralytic attack; sometimes loss of sight or hearing is the first indication; or a series of cerebral symptoms, for which it is difficult to assign an adequate cause: and this is often succeeded by impaired memory, and deranged mental powers, such as we have already alluded to. These cases generally result from disease, acute or chronic, affecting the brain, or its membranes, or from disease of the spinal cord. (See BRAIN, INFLAMMATION OF.)

Injuries of the spinal marrow in man and animals fully authorize the conclusion, that the higher in the spine the seat of injury is, the greater the extent of the consequent paralysis. Hence, then, we may reasonably expect that, in order to produce general paralysis, the spinal disease must be either of considerable extent, or situated at the upper part of the spinal marrow. This statement is confirmed by the cases (several of which are now on record) of rapid death following the separation of the atlas and axis, when a sudden compression is exerted upon the contained portion of the spinal marrow by the odontoid process.

The morbid conditions of the contents of the spinal canal which have been found coexistent with general paralysis, are pretty much the same as those of the brain and its membranes. They may be thus enumerated:—1. Inflammation of a considerable portion of the cord towards its upper part, the existence of which is generally indicated by ramollissement, suppuration, or abscess. 2. Extensive hardening of the substance of the cord, in which the membranes are more or less implicated. 3. Tubercles, or circumscribed tumours, developed in the spinal marrow. 4. Extensive serous effusion, probably an increase of the natural spinal fluid, as described by Magendie. 5. Thickening, or fungoid disease of the dura mater, and ossific growths, either in that membrane, or from the bony parietes of the vertebral canal.

In the present state of our knowledge of spinal diseases, it is not easy to assign any general symptoms which would point unequivocally to the spinal cord as the source of evil in certain cases of general paralysis. From all that has been collected on the subject, however, we think we are justified in asserting that there are certain phenomena which more frequently, or in a more marked manner, accompany paralysis resulting from spinal, than that which depends on cerebral disease. There is in these cases, generally, a more excited state of muscular action, evinced by spasms, twitchings, or even convulsions, and sometimes a permanent contraction. The sensibility of the surface, too, is often more deranged: thus, formication, tingling, or numbness, are very frequently found as the precursors of the form of palsy we are alluding to. We may further remark, that it is in cases of spinal disease that we sometimes see the line drawn with the greatest precision between the motive and sensorial powers; the latter being totally unimpaired, while the former is completely destroyed; a fact which seems clearly to direct us to the two distinct sources whence experimental physiology would derive these powers. Ollivier seems to think that diminution of temperature is more obvious in palsied limbs from spinal disease; and it would appear from the reports of cases by him and others, that they are more liable to œdema, vesication, sloughing, &c. In fine, the mode of access of paralysis dependent on spinal disease, is, for the most part, such as has been described as characteristic of the *creeping palsy* of authors.

We occasionally meet with cases of general palsy, well calculated to perplex the pathologist, presenting many indications of spinal disease; and yet, when we come to examine them after death, no lesion whatever is discernible, or at least a very slight one, obviously insufficient to account for the phenomena. We quote such a case from Dr. Abercrombie as a specimen, and it is further worthy of notice, as another instance of palsy almost universal. "A woman, æt. 20, a servant, sprained her back in lifting some heavy article of furniture. Some time after, she began to experience weakness of the legs, which gradually increased to perfect paraplegia. After some time the affection extended to the arms, and she then had not a vestige of motion of any of the parts below the head, except a very slight motion of some of the fingers; but the internal functions were all entire, and her speech was distinct, except that in speaking she was sometimes seized with spasmodic twitches of the lips and lower jaw. She lived in that state without any change in the symptoms, her general health continuing good, for about twenty years. In the morning she was taken out of bed and placed in a chair so contrived as to support her in a sitting posture. Her arms were supported on a cross board placed before her; and if by any accident one of them slipped from its support, she had no resort but to call the assistance of some other person to replace it. On one occasion the arm was allowed to hang for two hours, she having been left alone, and it became extensively œdematous. In the same manner, if her head fell forward upon the thorax, it remained in that position until raised by an attendant. Her mind was entire. She died of four days' illness with symptoms of typhous fever. I examined the body," adds Dr. A., "with the utmost care, along with Dr. Pitcairn, and *we could not discover any disease either in the brain or spinal cord.*" (*Abercrombie*, p. 417.)

Cases nearly similar as to the extent of palsy are recorded by Bretonneau and Ollivier, but in which a very slight morbid alteration was discovered. In one, the palsy commenced by loss of motion of the little finger, and rapidly spread to the extremities, the tongue, and partly to the muscles of deglutition. The patient, however, strange to say, retained the power of moving the thumb and two fingers of the right hand. In this case the only obvious morbid change in the nervous centres was, a rust-coloured spot three lines in extent upon the tuber annulare. (Revue Médicale, May 1826.) In Ollivier's case, a strong sense of pricking in the points of the fingers of the left hand, and toes of the left foot, was the first symptom. This was followed in half an hour by a similar sensation in the same parts on the right side. On the following day there was

general paralysis, but the sensibility was not impaired. Respiration and deglutition were considerably affected: the difficulty of respiration increased, and she died the third day. There was only a slight appearance of infiltration of blood in the cellular tissue on the outside of the dura mater of the cord, especially about the lower part.

Now and then cases of general paralysis, apparently dependent on the state of the spinal marrow, are observed to recover. Ollivier has recorded several examples of this kind. The palsy spreads from limb to trunk, commencing in the fingers and toes, and often preceded by tingling or formication, and more or less numbness of the cutaneous surface. The paralysis, although general in extent, is, however, rarely complete; the functions of the rectum and bladder are not at all or but slightly affected, and the intellectual powers are entire. In some cases the palsy is preceded by pains in the dorsal region of the spine, or a sense of fatigue, and lassitude and weakness of the spine. It has been observed to follow the stoppage of an habitual evacuation, abuse of sexual intercourse, and the suppression of the lochia in women after parturition. Such cases are supposed by Ollivier, and with much reason, to be occasioned by a temporary congestion of the vascular system of the spine, especially the venous system, so remarkable for its numerous and intricate anastomoses.* He conceives that, although the anastomoses are large and numerous, yet the circulation is often deranged and retarded; for, first, these veins are destitute of valves; secondly, he has found in old persons fibrinous clots filling all the venous ramifications of the spinal marrow, as well as those which accompany its nerves; and, lastly, he considers that respiration exerts a direct influence on this portion of the circulating system, and causes obstacles in it during efforts of various kinds, or strong emotions, or those affections which in a greater or less degree excite the respiratory act. (*Ollivier*, De la Moëlle Epinière, vol. ii.) As a venous congestion, such as we have been alluding to, is not likely to be a permanent morbid appearance, that is to say, might be dissipated under the influence of various causes, either immediately prior or subsequent to dissolution, it is not unreasonable to suppose that some of those cases in which no morbid change was discoverable, may have been attributable to a similar cause.

The general paralysis of lunatics, as described by Esquirol and Calmeil, has been already fully noticed in the articles Brain, Inflammation of the, and Insanity. We may here observe, however, that one of its earliest symptoms, viz. defective articulation, would alone serve to distinguish it from palsy dependent on spinal disease.

It is hardly necessary to advert to the propriety of observing great caution in forming a prognosis of any or all of the forms of general palsy now described. The difficulty of arriving at a certain diagnosis of the proximate cause must necessarily involve the practitioner in considerable doubt.

II. Partial Paralysis.—Under this head are included those varieties of paralysis in which only a part of the body is engaged; it admits of a threefold division — 1. local paralysis; 2. hemiplegia; 3. paraplegia.

1. **Local Paralysis.**—This division comprises all those palsies which have their seat in parts of small extent. Local palsies are most frequently met with as precursors of a more extended condition; yet we sometimes find them localized as well in cause as in extent. In the former case they should be regarded with great suspicion, and should excite a vigilance on the part of the practitioner to counteract, as far as possible, the threatened danger; hence the importance of distinguishing accurately between local palsies under these different circumstances.

We shall notice local paralysis under the following heads: 1. paralysis of the eyelids; 2. paralysis of the face; 3. paralysis of a limb or part of a limb; 4. paralysis of particular sets of muscles, or of single muscles.

Paralysis of the Eyelids. — Two forms of palsy are found to affect the eyelids, which, as engaging antagonist muscles, are totally opposite in their effects. In the one, the eye remains totally or partially closed (*ptosis, blepharoptosis*); in the other, the eyelids are permanently open, the patient having lost in a greater or less degree the power of closing them (*Lagophthalmia*).

Ptosis has been so named from its chief and most conspicuous phenomenon, viz. the drooping or fall of the upper eyelid; it occasionally comes under the care of the surgeon as arising from a relaxation and extension of the common integuments of the lid and consequent folds of the skin, by which the energy of the *levator palpebræ superioris* muscle is somewhat but not very considerably diminished. (Weller's Manual of Diseases of the Eye, by Monteath, vol. ii. p. 97.) But that form which we are about to notice, is dependent essentially on palsy of the muscle above-named, owing to some affection of the nerve which supplies it. It has been named *blepharoplegia* by the Germans, the patient being unable by any voluntary effort to raise the upper lid, although the power of closing the lids remains entire. It is therefore the object of the practitioner to ascertain in the first place whether this condition of the eyelid be merely produced by the mechanical cause above alluded to, and, secondly, if it be connected with a deranged state of any of the muscles of the eyelid. To decide the first question, we would adopt the proposal of Scarpa. "If," he observes, "the atony or complete paralysis of the elevator muscle of the eyelid have had any share in producing the relaxation of it, it may be known by making a transverse fold of the integuments with the fingers or forceps near the superior arch of the orbit. For if this muscle has not lost its power of contraction, when it is relieved, as it were, from the superincumbent weight of the integuments, the patient is able to raise the eyelid and open his eye sufficiently; if otherwise, the eye remains half closed." (*Scarpa*, by Briggs, p. 127.) Such a proceeding, it is obvious, must at once determine the state of the *levator palpebræ* muscle; but it should be remembered that a spasmodic state of the *orbicularis palpebrarum* muscle may likewise produce the appearance of fallen lid. The want of perma-

* If the reader can have access to the beautiful and accurate plates of Breschet, "Du Système Veineux," he may from them form an adequate conception of the extent and intricacy of the veins of the spine.

nence of this affection, the occasional power of raising the lid, and the degree of resistance which is always made by the spasmodic state of the orbicular muscle to any attempt to open the lids, will in general be found sufficient to indicate the precise nature of the affection.

Secondly, the practitioner should direct his attention to the motions of the eye-ball. It rarely happens that the fallen lid is a solitary affection; in general, and when it does not depend on either of the causes above named, we find a paralysis of most of the muscles of the eye complicated with it. The patient, it will be observed, has no control over the voluntary motions of the eye-ball; when told to look to the ground, he is unable so to do, and the same inability is manifested when directed to look upwards or inwards. If the eyelids be forcibly opened and held apart, and the patient be desired to endeavour to close them, the eye-ball is seen to turn upwards when he makes the effort. Sometimes the power of looking outwards is retained, and in some instances a strabismus in that direction is present.

A moment's reflection will show that symptoms such as we have now detailed can only be produced by a palsied state of the third nerve. The muscles supplied by the nerve are paralysed, and the eye-ball exhibits motion in only two directions. One of these is abduction, performed by the external rectus which is supplied by the sixth nerve; the other is to be regarded as an involuntary action, instinctively coexistent with the effort to close the eyelids: it is that by which the eye is turned upwards, and, according to Sir C. Bell, is caused by the combined action of the obliqui, (See Appendix to Bell on the Nerves, p. xxxix. et seq.) although in such a case as we are now considering, it is difficult to conceive the inferior oblique muscle can be exempt from that paralysis into which all the other muscles supplied by the third nerve had fallen.

Ptosis, attended with such an imperfection of the motions of the eye-ball, is to be regarded in general as a formidable affection; it is very frequently indicative of cerebral disease, and therefore is often witnessed as a precursor or accompaniment to hemiplegia. Sometimes it is merely the result of local compression of the nerve by a tumour within the orbit. There are occasionally present symptoms indicating more extensive disease, the sensibility of the eye being destroyed, as well as of the integuments supplied by the ophthalmic portion of the fifth nerves, or even of the whole side of the face. Such a case was that related by Mr. Shaw in the twelfth volume of the Medico-Chirurgical Transactions.

If the affection which we have thus briefly noticed be dependent on cerebral disease, the treatment must be directed accordingly; it is obvious that when it is caused by a tumour in the orbit, it is almost completely beyond the control of medicine. Cases may occur in which the propriety of a surgical operation may become a question: we shall only remark on the necessity of observing due caution, lest by converting a closed state of the eyelids into a permanently open one, we thereby endanger the safety of the eye-ball, from its unavoidable exposure to irritating particles.

The second form of palsy of the eyelid is that in which the patient is unable to wink or close the lids. It has been denominated *lagophthalmia, vue de lièvre, oculus leporinus,* from the vulgar notion that the hare sleeps with its eyes open. In these cases the eye remains permanently open, even during sleep, the orbicularis palpebrarum muscle being paralysed. The eye-ball projects to an unusual degree from the socket, owing to the absence of the accustomed resistance from the lids, and if the patient be directed to attempt to close the lids, the eye-ball is instinctively turned up with the effort so as nearly to conceal the cornea; nor is he conscious of that action. As winking can only be performed by drawing down the lid with the hand, free access is allowed for particles of dust, &c. to the surface of the eye, which, being likewise constantly exposed to the air, is necessarily subjected to much irritation and consequent inflammation.

This form of local palsy is chiefly worthy of attention from the contrast afforded by it to that last described; it is unquestionably dependent on disease of the portio dura nerve, and therefore is for the most part only a symptom of a paralytic affection which comes under our next head.

Paralysis of the Face.—The muscles of the face receive their nervous supply from the fifth, as well as from the portio dura of the seventh, pair of nerves. Of these, as is now pretty generally admitted, in conformity with Sir C. Bell's views, the former is a compound nerve, conveying sensibility as well as the power of voluntary motion; the latter directs the actions of the muscles in relation to the respiratory act. We have already alluded to the loss of sensibility of the face; it remains to notice these two distinct forms of partial palsy of the face, according as the motive portion of the fifth or the portio dura is the nerve affected.

Reasoning *à priori*, it is quite obvious that palsy of the fifth must produce a set of phenomena very distinct from those resulting from palsy of the portio dura. All voluntary power not only over the features, but also over the motions of the jaw, must be lost on the side affected; whilst, if the latter nerve be in a state of integrity, those motions of the facial muscles which are in accordance with the act of respiration are unimpaired. Mastication is impeded not only by the imperfection of the grinding motions of the jaw, but also from the loss of power in those muscles which place the morsel under the operation of the teeth; "in chewing, the action is only on the *sound* side of the head; the masseter and temporal muscles of the *affected* side do not rise or bulge out as in their natural actions, while there remains a perfect command over the features through the operation of the portio dura." (Bell on the Nerves, p. 106, 4to edition.) The distortion of the countenance is not very great; the jaw hangs on the affected side, and the angle of the mouth is depressed, that of the other side appearing to be slightly raised; the distortion is moreover either removed or greatly diminished when the patient laughs or smiles, an effect which all excited states of the act of respiration tend to produce. The condition of the face now described is that most commonly seen in hemiplegia; it is rarely met with unconnected with a more extensive palsy,

and when it does occur, the sensibility of the face and eye-ball, nostrils and tongue, is very generally impaired or destroyed. The disease of the fifth nerve may be seated either within the cranium immediately in connection with its ganglion, or there may be cerebral disease.

In those cases where the portio dura is the seat of disease, [*Bell's palsy,*] there is no evidence of the existence of palsy till those actions are called for, to the performance of which the palsied muscles ought to contribute. So long as the patient remains quiet, without speaking or smiling, nothing remarkable is observable in the countenance; but when any of the actions of excited respiration, laughing, sneezing, coughing, crying, &c. are produced by the sound muscles, the marked deformity of the countenance becomes apparent. The mouth is drawn to the sound side; and it may be observed in general that the disorder of the features is directly as the intensity of the respiratory act: thus laughing produces greater deformity than smiling. The affected cheek remains motionless, while, to use the expressive words of Mr. Shaw, the face on the other side "seems convulsed with laughter." The patient cannot snuff up with the nostril of the paralysed side; blowing or whistling is imperfectly performed, or failed in altogether. On further examination it will be found that voluntary motion still exists in the muscles of the face and jaw, varying, however, in degree in each, according as the voluntary action of the muscle is more or less connected with respiration. Thus mastication is perfect; here the buccinator performs its office fully as a muscle of mastication, and in one striking case related by Mr. Shaw the child even preferred chewing her food with the affected side. The voluntary action of the muscles influencing the motions of the mouth are not so distinct as those of the muscles of the jaws. Although, when an attempt is made to whistle, it proves completely ineffectual, yet the patient can "purse up" the mouth so as to hold a whistle or a pencil by the action of the orbicularis oris muscle. A slight power remains of elevating the angle of the mouth, and an analogous power can be exerted over the muscles of the forehead.

It is in the cases to which we are now alluding that we meet with that condition of the eyelids termed *lagophthalmia*, and it generally forms one of the most painful and distressing features of the case, in consequence of the constant irritation to which the eye is exposed. Articulation is sometimes affected in this form of local palsy; the patient learns from experience that by supporting the paralysed cheek with his hand the defect can be in some degree remedied. It is clearly important to distinguish between defective articulation arising from this cause, and that from palsy of the muscles, of the tongue, or larynx. The wasting of the paralysed muscles is equally conspicuous in this as in other forms of palsy, and in cases of old standing gives such a peculiar appearance to the countenance, as could hardly fail to direct an experienced observer to the true nature of the complaint. Mr. Shaw, in relating the particulars of a case, writes thus: "There is a remarkable wasting of all those muscles of the face which are subservient to respiration and expression. His cheek is so thin that when he speaks it flaps about as if it were only skin, and the corrugator supercilii and occipito-frontalis, which are principally muscles of expression, are so wasted that we might at first sight suppose they had been removed by operation, and that now the bones were only covered by skin." (Med.-Chir. Trans. vol. xii.)

Several opportunities have now occurred of ascertaining the cause of the palsied state of the portio dura. In many instances it has been suddenly produced by the influence of cold; the affection, as resulting from that cause, was long known under the name of *blight*. An inflamed state of the parotid gland, a tumour in the neighbourhood of the stylo-mastoid foramen, or an ulcer over the course of the nerve, have been found severally to cut off the nervous supply. Wounds of the portio dura, whether from accident or the surgeon's knife; disease of the petrous bone, engaging the aqueduct of Fallopius; inflammation of the internal ear; or a tumour compressing the nerve at its entrance into the internal auditory foramen, may likewise be reckoned among the causes. In fine, this form of palsy may have its origin in disease of the brain.

The symptoms above detailed are such as arise from a palsied state of either the fifth or seventh nerve, the other being perfectly free from any disease. Symptoms, however, so exclusively denoting an affection of a particular nerve of the face, are not frequently to be met with, and then only at a short period after the invasion of the palsy; for if the disease be of any continuance, the palsy is apt to spread, as it were, to the unaffected nerves. This is more especially the case when the portio dura is primarily affected, the slight degree of voluntary power over the muscles of expression gradually disappearing, but not from those of mastication. When the fifth nerve is the primary seat of disease, the branches of the portio dura retain their integrity for a much longer period, and in some instances do not exhibit any mark of disease; but in many cases, where the palsy has been of long duration, the extent of the disorder of the countenance can hardly be accounted for, except on the supposition that the disease has extended to the filaments of the portio dura. We think that a careful observation of the countenances of individuals who have been hemiplegic for some time, will sufficiently confirm this statement.

It is rare to meet with palsy of both nerves at the same time.* When such is the case, there must obviously be a modification in the symptoms dependent on the complete resolution of the muscles of mastication as well as of expression. The characteristics of the countenance of the hemiplegic will be conjoined with the strangely-disordered expression resulting from the diseased portio dura.

In the treatment of local palsies of the face, especial attention should be directed to ascertain the state of the brain. If there be reason to suspect that the origin of the complaint is there, of course the treatment will be directed to that quar-

* See a case by Dr. Abercrombie, in which the fifth nerve was paralysed on one side of the face, and the portio dura on the other, occasioned by a tubercle in the brain. On the Brain, p. 178.

ter. If otitis, or the pressure of a tumour externally, be the cause, then the proper remedies to subdue the inflammation in the one case, and to promote the absorption of the tumour in the other, must be had recourse to. External stimulants, blistering, directing the steam of boiling water to the face, local bleeding, will be found useful, but especially in the cases which have been caused by cold. The application of strychnine to a blistered surface has proved successful in some cases; the eighth, fourth, or half a grain may be applied on the dressings. We may here observe that the acetous preparation of cantharides, rubbed on to the part with a camel-hair pencil, will be found a very convenient and cleanly mode of producing vesication on the face in these cases. Electro-puncture has been practised with great success by Pichonniere in several cases of this kind; the needles having been sunk in the vicinity of the branches of the diseased nerve. (Pichonniere sur la Paralysie particlle de la Face: Paris, 1830.)

Paralysis of a limb or part of a limb.—In children, palsy of a single limb (generally an upper limb) is not uncommon; sometimes dependent on a deranged and loaded state of the bowels, sometimes on disease of the brain, and occasionally from congenital deficiencies in that organ: in such cases, if the child grow up, we see, to use the expressions of Sir C. Bell, the limb of a child as it were unnaturally joined to the body of an adult.*

A peculiar form of palsy of the upper extremity is described by Dr. Healy, in the third volume of the Dublin Hospital Reports. "The affection alluded to attacks persons of all ages, males and females being equally liable to it. Prior to the attack, the patient generally enjoyed good health; consequently he is not a little surprised, on awaking from a long and sound sleep, to discover total loss of power of one hand; and, what is remarkable, he generally describes the loss of power as extending to the middle of the fore-arm: in some few cases it extends to the elbow, and is accompanied with a great sense of numbness. The fingers are so completely paralysed that the patient is deprived of their use: great dejection of spirits attends the complaint." No cause could in general be assigned for these symptoms, unless the pressure upon the nerves occasioned by lying with the head resting on the arm; an opinion confirmed by the fact that in many the palsy succeeded to sleeping in a chair in that position. Dr. Healy further remarks, that "this affection has invariably yielded to electricity."

Dr. Darwall has described a species of paralysis affecting the upper extremity, most of the individuals attacked having been in the habit of lifting heavy weights. In some of the cases the palsy at first occupied the muscles connecting the humerus to the scapula, especially the deltoid, which was wasted; there was, therefore, inability to raise the arm, but the power of flexing the fore-arm remained. After some little time, total paralysis of the upper extremities gradually supervened. In one case of this kind, the patient continued for eight years without any use whatever of his upper extremities. In some of the cases the paralysis did not descend below the muscles of the shoulder. Considerable pain in the deltoid muscle generally preceded the paralysis, and one or two of the cases yielded readily to treatment in that stage. Dr. Darwall considers this affection as "one primarily engaging the nerves supplying the elevating muscles; and that they may have been injured by the straining necessary in raising or carrying heavy weights." (Lond. Med. Gazette, vol. vii. p. 201.)

A case in some degree analogous to those last alluded to is recorded by Dr. Abercrombie; it is that of a young lad aged 14, who had nearly lost the muscular power of the upper part of both his arms, accompanied by a most remarkable diminution of substance of the principal muscles. The deltoid and biceps were reduced to the appearance of mere membranes, and the muscles of the scapula were found nearly in the same state; the affection came on gradually, without any sign of spinal or cerebral disorder.

Local palsy seated in either extremity, or part of an extremity, is mostly, as all other forms of local palsy, found as the first step or stage to a more extended affection. In such cases there is frequently some indication to direct the practitioner to the true source of the complaint. It is not uncommon to meet with instances where palsy affects only a few of the muscles of an extremity. The muscles affected are, as Sir C. Bell† observes, generally those which are naturally combined in action; although those muscles be in different parts of the extremity, and are supplied by different nerves as they are by different arteries; of which an obvious example may be taken from the case of paralysis of the short muscles of the ball of the thumb, in which the palsy also extends to those muscles of the thumb which lie on the fore-arm. Sometimes all the extensor muscles will lose their power, while the flexors preserve it. This seems to be the case in a patient alluded to by Dr. Bright. She had no power of extending her hands; they were precisely in the condition of the "drop hand" from the paralysis caused by lead. She could carry her child between her fore-arms and arms. Sir C. Bell has found the action necessary for writing gone, or the motions so irregular as to make the letters be written zigzag, whilst the power of strongly moving the arm or fencing remained.

It may be asked, what is the condition of the nerves in these cases of local palsy? Some instances have presented symptoms in the commencement indicating an inflammatory state of the nerve or its neurilemma, which has been further confirmed by the success which has followed local depletion and other antiphlogistic remedies in such cases. It is not rare to see a palsied and atrophied state of the lower extremity succeed to inflammation of the sciatic nerve. In a case by Shaw, palsy of the extensors of the fingers and thumb succeeded to tight bandaging after a dislocation of the shoulder, and was evidently caused by inflammation of the musculo-

*See a case by Rostan, "Sur le Ramollissement du Cerveau," obs 1. p. 256. Also cases by Cazauvieilh in his memoir "sur l'Agénésie cérébrale," Archives Gén. de Médecine, 1827.

†On the Nervous System; Appendix, p. clx. The reader will find in the appendix to this work a valuable and highly-interesting collection of facts connected with all the varieties of local palsy.

spiral nerve. (Med.-Chir. Trans. vol. xii. p. 132.) Dr. Bright has given a case in which complete paralysis of the fore-arm resulted from the pressure on the nerves produced by a badly united fracture. Paralysis from pressure on a nerve in various ways is common. Dr. Abercrombie mentions a case of paralysis of the fore-arms and hands of both sides, induced by pressure in consequence of leaning for a long time upon a bar of wood, while the person was stooping forward in his anxiety to witness some public exhibition.

There are cases of local palsy affecting the extremities, or parts of them, in which the state of the circulation in the limb seems a more probable cause of the attack than any primary disorder of the nerves: such are those cases detailed by Dr. Storer, Dr. Abercrombie, and others. The sudden accession of considerable pain in the part is the first symptom; this is succeeded, after a variable interval, by paralysis. The cessation of pulsation in the principal arteries of the limb, with the coldness and numbness which attend the palsy, seem strongly to point to the arterial system as primarily diseased. In Dr. Abercrombie's case, post-mortem examination proved that the arterial system was extensively ossified; and in many places the arteries were obstructed by firm coagula. Drs. Graves and Stokes have also given a case of paralysis of one of the lower extremities from marked disease of the common iliac, femoral, and profunda arteries of the same side, those vessels being completely plugged up by a dark clot, which likewise extended into many of their ramifications. (Dublin Hospital Reports, vol. v. p. 1.) There are paralytic states of the extremities connected with rheumatism and gout, for an account of which we refer to the articles on those diseases.

Paralysis of sets of muscles or single muscles.—The muscles concerned in the act of deglutition are sometimes affected with paralysis, but in general towards the close of an old paralytic affection of great extent. Some few cases, however, are recorded in which these muscles were alone paralysed. A well-known case of this kind is that described by Mr. Hunter. (Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge, vol. i.) The patient had laboured under a train of nervous symptoms for some time; one morning he awoke with a sense of choking, a numbness of the right side, together with a paralysis of the muscles of deglutition, which deprived him of the power of swallowing. The palsy did not extend; and this patient owed his cure to the judicious employment of an elastic tube introduced into the œsophagus, by which food and medicines were administered, thus obviating the effects of the palsy. Hysterical palsy sometimes assumes this form, giving rise to dysphagia. The muscles of the larynx may be likewise palsied, giving rise to a species of aphonia: this likewise frequently takes place in hysterical cases. Palsy of the tongue, as a solitary affection, is of very rare occurrence. Sometimes one-half of it is paralysed in consequence of pressure on the ninth nerve upon that side; as in a case related by Dupuytren in his Leçons Oracles, in which a hydatid compressed this nerve, producing paralysis and atrophy of the same side of the tongue.

Single muscles are frequently the seat of paralysis, in general occasioned by pressure upon the nerve which supplies the muscle. The palsy of the deltoid from pressure on the circumflex nerve by the dislocated head of the humerus, is a case familiar to every surgeon. Palsy of the sterno-mastoid muscle may give rise to all the characters of wry neck. Paralysis of the serratus magnus anticus muscle from pressure on or injury of the posterior thoracic nerve (external respiratory of Bell) gives rise to a remarkable set of phenomena, with which, as liable to lead him to mistake the complaint for something more serious, the practitioner ought to be acquainted. Two cases of this affection are on record; one by Gendrin, the other by Velpeau. In Gendrin's case, there was a marked deformity produced by a tumour seated at the superior dorsal region of one side, and which was evidently formed by the posterior edge of the scapula pushed firmly backwards; it appeared without any assignable cause in the course of a few days. The power of drawing the scapula forwards, and elevating the prominence of the shoulder, was lost; and when both rhomboid muscles were made to act fully, and to approximate the scapulæ posteriorly, the tumour disappeared completely. This case had been mistaken by two medical men for distorted spine. The patient recovered after a few weeks, under the successive application of blisters. (See Gendrin's French translation of Dr. Abercrombie's work on the Brain, p. 646.) In Velpeau's case the palsy was caused by violence inflicted on the nerve in its passage along the inner wall of the axilla. (*Velpeau*, Anat. Chirurg. vol. i. p. 303.)

Many forms of strabismus are occasioned by a palsy of one or more of the muscles of the eyeball; the sound muscles thus obtaining a predominance of action.

The internal muscles, those of organic life, are sometimes palsied. The circular coat of the intestines is no doubt frequently the seat of paralysis; an opinion which would seem to be confirmed by the frequent occurrence of paralysis of the sphincter ani.

Paralysis of the bladder, from prolonged overdistension, frequently comes under the surgeon's care. In such cases, as well as in that connected with paraplegia, there is *retention* of urine. *Incontinence* of urine is in some cases, in old persons especially, to be regarded as dependent on a paralysed condition of the fibres which act as a sphincter to the neck of the bladder. (*Boyer*, Maladies Chirurgicales, vol. ix. p. 274.)

Treatment.—The treatment of the last two classes of local palsy should be conducted on similar principles to those laid down in speaking of paralysis of the face. Of course the palsied states of the bladder will require a distinct plan of treatment, chiefly surgical. Paralytic limbs may be benefited by local treatment, to which we shall refer more at large in another part of this article.

2. **Hemiplegia,** (ἥμισυ, *dimidium*, and πλῆσσω, *percutio*,) *semisideratio.* The term is applied to denote paralysis existing only on one side of the body, and affecting not less than the upper and lower extremities. Some have employed it in alluding to paralysis occupying the upper and lower extremities of opposite sides; but that form of

palsy may, with less risk of confusion, be denominated *crossed or transverse paralysis* (paralysie croisée).

Hemiplegia is by far the most frequent species of palsy met with in practice; and it has been stated, upon the authority of Sir Gilbert Blane's comparative observations, that it occurs more frequently on the left than on the right side; the proportion being as three to two. (See also Dict. des Sc. Méd. art. *Paralysie.*) In general the paralysis affects the side of the face as well as the extremities; the angle of the mouth is drawn to the sound side, and more or less upwards; the tongue is frequently half paralysed, as is rendered evident on its protrusion, when it presents a curve, the convexity of which is towards the affected side: sometimes it is only sluggish as it were, the patient not having the full power of protrusion. The muscles of deglutition are frequently more or less engaged. The mode of progression of a patient labouring under hemiplegia is remarkable. He is said to "drag the leg," the paralysed lower extremity being moved along, or perhaps propelled, by the inclination of the trunk to the sound side; the foot is generally pointed outwards, and when the limb is raised it falls as it were by its proper gravity, presenting that remarkable pointing of the foot which cannot fail to have attracted the attention of any who may have observed a hemiplegic patient walking. The arm of the affected side generally is adducted to the trunk, and the fore-arm appears slightly flexed upon the arm, the wrist and fingers being likewise in a slight state of flexion.

Considerable variation is observable in the manner in which hemiplegia appears. The symptoms which precede or accompany its invasion claim much attention from the practitioner, as being his chief guides in the formation of a correct prognosis, as well as in the application of suitable treatment.

1. Hemiplegia is the most common form which paralysis assumes from effusion of blood within the cranium. When the coma of the apoplectic seizure is removed, and consciousness is restored, the patient is generally observed to be hemiplegic.

2. Hemiplegia sometimes appears suddenly without previous indication, and with or without stupor: in such case it is most frequently a precursor of apoplexy. (*Abercrombie*, p. 14.)

3. A third variety is that in which symptoms more or less painful in their character precede the paralytic attack: pain in the head, with fever of variable duration and intensity; more or less disorder of the intellectual powers; spasmodic twitchings of the muscles; muscular stiffness; convulsions, ending in hemiplegia, with considerable pain in the paralysed limbs.

4. Another form occurs chiefly in persons past the meridian of life. The patient is observed to be morose, heavy, and drowsy; his digestion is disordered; memory and intellect are impaired; there is a loss of one or more senses, usually sight or hearing; then sudden loss of speech, difficulty of protruding the tongue, followed by paralysis of half of it; distortion of the face; complete hemiplegia.

5. A train of symptoms of an anomalous, and to the physician, a perplexing character, sometimes precede the hemiplegia: viz. headach, nervous excitability, deranged functions, with a number of uneasy sensations referable to various causes. The patient continues to complain; nor is the obscurity of his condition removed till paralysis begins to develop itself either by suddenly attacking one half of the body, or by creeping on from some remote part. It is with such cases as these that we occasionally observe symptoms resembling chorea, or fits of an epileptic character. The writer has lately seen a child in whom there is an incomplete hemiplegia, the lower extremity being completely paralysed, the upper partially so: there is also a convulsive action of the flexor muscles in the fore-arm, and a convulsive protrusion of the tongue, taking place almost every two minutes; there is slight ptosis of the eyelid, but the features are regular. The case of the celebrated M. de Saussura is one somewhat in point. (See Med.-Chir. Trans. vol. vii.)

6. Hemiplegia is occasionally met with at some period after the receipt of an injury of the head. We remember such a case in the person of a gentleman about forty years of age, who about two years previously had been severely wounded in the head by highwaymen. The hemiplegia, which came on gradually, and was on the side opposite to that on which the injury had been inflicted, was complete, and resisted every kind of treatment. The case proved fatal, but the body was not examined after death.

The morbid state of the brain, with which hemiplegia in the above-mentioned varieties is connected, have already been sufficiently dwelt upon in the article Brain, Inflammation of the. In fact, there is no diseased condition of either the brain or its membranes with which this form of palsy has not been found coexistent. With a few exceptions, not altogether to be relied upon,* the disease has been found on that side of the brain opposite to the seat of the paralysis. That this should be the case, anatomy would lead us to expect; the interlacement or decussation of the fibres of the anterior columns of the spinal marrow (*corpora pyramidalia*) at their summits being now generally admitted, and easily demonstrated. According to the views of Foville and others, we should likewise expect to find the optic thalami and corpora striata, or some of the fibrous radiations which pass through these bodies, the seat of disease in hemiplegia. And in point of fact we must admit, that in the generality of cases of this description, those bodies, or some portion of the cerebral hemisphere, present a morbid alteration of structure variable in extent as well as in degree. Cases, however, it must likewise be admitted, do occur, in which only one of the bodies above-mentioned is the seat of disease, or in which no appreciable alteration can be detected in the hemisphere. Such occurrences can hardly be deemed as decidedly to militate against the theory of Foville, &c. inasmuch as our ignorance of the mechanism of cerebral action, whether healthy or

* See the cases of Bayle, Revue Médicale, 1825; one by Bright, (Reports on Diseases of the Brain,) which the author himself admits to be a "doubtful exception;" and Morgagni, lib. 1. epist. ii. § 16. The most complete exception with which we are acquainted is one mentioned by Cazauvieilh, Archives Gén. de Médecine, May 1827, p. 15-16.

morbid, is alone sufficient to render them anomalous to us. They should, however, increase our caution in receiving speculations upon the uses ascribed to the different portions of the brain, and should excite us to increased accuracy of detail and minuteness of inquiry upon these points of pathological anatomy.

Hemiplegia may be induced by diseases of the upper part of the spinal marrow, the morbid alteration being on the same side with the paralysis. Such cases are rare, however; for it is seldom that disease would be exactly limited to a lateral half of the marrow. In general, when they do occur, the hemiplegia is only a precursor of the general paralysis above described. Dr. Bright, (Op. Cit.) Ollivier, and Velpeau (Archives Gén. de Méd. June 1825,) give cases of this description; and in the Edinburgh Medical and Surgical Journal for April 1825, a case is related where hemiplegia resulted from concussion of the spine, accompanied with complete anæsthesia of the other side of the body. The paralysis of motion did not extend. (See also a case by Portal, Anat. Méd. tom. iv. p. 116.)

Cazauvicilh has published two interesting memoirs on *congenital* paralysis, by which he would signify that which appears at birth, or a short time after it. To the cerebral alteration on which the paralysis depends he has given the name "*agénésie cérébrale*," denoting a defect of development or of growth in the brain or any of its parts. In the majority of the cases detailed in these memoirs, the paralysis was in the form of hemiplegia, the limbs were greatly wasted, stunted in growth, and with many in a state of permanent flexion. The upper extremities were generally more altered than the lower; in many cases they were bent and contracted, the elbow, wrist, and fingers being flexed. Among the muscles of the lower limbs, those of the calf of the leg chiefly presented the phenomenon of contraction, and thereby kept the foot permanently extended. The paralysis was complete in only a small number of cases. The organic defects were as follows: a depression on one side of the cranium indicated a corresponding want of development of the subjacent cerebral hemisphere, — a deficiency further proved by the flattened, non-developed appearance of its convolutions, the difference of size from the hemisphere of the other side, the less capacity of the ventricle, as well as a slight diminution in the dimensions of the corpus striatum and optic thalamus. The cases observed by Cazauvieilh were mostly in persons who had arrived at an advanced age. (See Archives Gén. de Méd. for May and July 1827.)

Intermittent Hemiplegia.—A form of hemiplegia, which may be denominated *intermittent*, has been alluded to by Sauvages, Morgagni, and Cullen. Sauvages, by whom the species has been particularly noticed, describes it as coming on every day, and after some hours receding, with an accession of quotidian fever; and he gives a minute account of a case of this kind. The case described by Morgagni was that of a woman aged forty, who, after severe and long-continued headach, became completely hemiplegic; when thus affected, she was likewise seized with the same kind of palsy *on the healthy side* every day towards the evening, which went entirely off as the morning came on. After this disorder had attacked her seven or eight times at nearly the same hour; she died of pneumonia. There was no examination of the body. (See Cooke on Palsy, p. 20.)

A case of this description is recorded by Dr. Elliotson. (London Medical Gazette, vol. vii. p. 486.) The patient, forty-eight years of age, had been in the East and West Indies, and had had fever at Bombay and at Batavia, and had suffered from dysentery and diarrhœa. For two years and a half previous to his admission into St Thomas's Hospital he had been subject to paroxysms, which threw him into the condition of a perfect hemiplegic; totally losing the power of his arm, and "dragged his leg in a semicircular way, as patients usually do when labouring under hemiplegia." The paroxysm began at ten o'clock on every third or fourth morning, and lasted in its full force from three to four hours; "but although it lasted only that time, he was not perfectly clear from it the whole day." The man had a sickly aguish look, and very much the appearance of one who had suffered from a hot climate. Under the supposition that the patient's complaint arose from malaria, he was treated with large doses of sulphate of quinine, five grains every sixth hour, afterwards increased to ten grains. The effect of the medicine was a decided improvement in the general health, and a considerable increase in the intervals between the paroxysms. It does not appear that a perfect cure was effected.

Prognosis. — We believe it is quite consonant with the results of general experience to state, that hemiplegia, connected with an apoplectic condition of the encephalon, is that which is most likely to recover. That the effused blood may be absorbed and leave nothing to indicate the situation it occupied, but a small cavity, is now abundantly proved. But in cases where there is no effused blood, it is obvious that less difficulty exists to restore the brain to its healthy condition, and in these cases accordingly we frequently find the paralysis yield readily and even quickly to treatment. When the effusion has taken place, we sometimes see the disappearance of the palsy and the absorption of the coagulum to proceed *pari passû;* but such an event does not occur so frequently as we might, *à priori*, be led to expect. It sometimes even happens that the coagulum has been completely absorbed, and yet the paralysis continues in no degree diminished. The writer has in his possession a portion of brain of a girl twenty-two years of age, who had been hemiplegic after apoplexy, and continued so, without any recurrence of apoplexy, till her death, one-half of the body being *completely* paralysed. The brain was healthy, with the exception of a small cavity not exceeding four or five lines in diameter, situated about the centre of the left hemisphere, lined with a brownish-coloured membrane, and containing a serous fluid of a similar colour. In fact, it would seem as if, after a certain period, the cerebral lesion and the palsy lost their relation to each other as cause and effect, and the latter continues, as it were, independent of the condition which originally gave rise to it.

[In rare cases of cerebral hemorrhage, there is no paralysis. Cases of this kind occurring to

others, and one occurring to the writer, are referred to elsewhere. (*Practice of Medicine*, 2d edit. ii. 187, Philad. 1844.)]

Treatment of Hemiplegia.—The treatment of hemiplegia varies according to the time which has elapsed since its accession. If the patient be seen immediately after the appearance of paralysis, the practitioner must look accurately to the condition of the nervous system, directing his remedies to that which appears to be the seat of the disease. These remedies, though few, are, when appropriately applied, powerful, and in the diversity of lesions which give rise to the affection under consideration, require the exercise of much judgment and discrimination, in order to their successful employment.

The principal treatment, then, in this early stage of hemiplegia, will depend on the precise nature of its cause, on the general condition of the patient, his age, and previous state. Bleeding, purging, and other antiphlogistic remedies may be adopted where there is decided evidence of plethora, inflammatory or apoplectic. How far these measures may be carried with safety or advantage, the circumstances of each particular case can alone decide; in general, however, it will be found necessary to employ them to some extent, so as to produce a decided effect upon the system of the patient. When all inflammatory symptoms have been reduced, a mild mercurial treatment has often proved extremely useful. Does it in apoplexy promote the absorption of the coagulum? Dr. Prichard observes, respecting the use of mercury in hemiplegia, "that those patients, in whom a slight degree of ptyalism has been produced, have almost uniformly appeared to him to derive material benefit from it, and their recovery has been more complete than that of others in whose cases the same remedy has either not been used or has not been administered to the same extent."

Due attention must of course be paid to regimen. Abstinence from all stimulating elements, solid or fluid, must be rigidly observed in the great majority of cases. In a more advanced stage of hemiplegia, where the urgency of the brain symptoms appears to be either diminished or removed, and where the palsy is the object chiefly worthy of attention, the physician has in view a twofold object,—to prevent a recurrence of head symptoms, and, secondly, to alleviate the condition of the limbs. The former end is to be attained more by avoiding what has a known injurious tendency than by adopting any particular plan of treatment; this, however, is not to be neglected, as a proper regimen does much towards maintaining a uniform state of the general system: we may add that in this stage especial benefit will be derived from allowing the patient to enjoy air and exercise as much as he is able to bear. Change of air and scene are unequivocally of decided advantage, and a visit to some watering-place is often made in this stage of the complaint with marked benefit. Mental serenity and a freedom from the cares of business are indispensable.

To alleviate the condition of the paralysed limbs, the treatment may be applied to the seat of the original disease as well as to the limbs themselves. Thus, with a view to act upon the seat of the primary disease, we have recourse to counter-irritation in the vicinity, or, as some prefer it, more remotely. For this end, we employ setons, issues, blisters, tartar-emetic ointment, or tartar-emetic in powder, sprinkled on the dressings applied to a blistered surface; frictions with liniments containing various irritating substances, among which we may mention the croton oil, as being an extremely severe irritant. Dr. Prichard highly extols the practice of inserting a large issue in the scalp in cases of this kind; he advises an incision to be made completely through the scalp for four or five inches over the sagittal suture, and the edges of the wound to be separated by a row of peas. (Lond. Med. Gazette, vol. vii. p. 427.)

The treatment of the paralytic limbs consists in the use of stimulating applications, with the idea that a stimulus applied to the sentient extremities of the cutaneous nerves may have the effect of rousing from their state of torpor the more deeply-seated trunks. Of these external stimulants we may enumerate the following; dry friction with the hand or by the flesh-brush, a remedy much approved by Dr. Cooke; warm baths; stimulating liniments, prepared of the concentrated acids or the caustic alkalies combined with oil or lard; brine, or a strong solution of sea-salt; terebinthinate applications; sinapisms; blisters. Dr. Cullen has found the use of liquid styrax, in the proportion of one part to two of the old black basilicon, remarkably serviceable in paralytic cases. The application of cold has been recommended, and we have known it beneficial when applied daily in the form of a shower-bath. Some more simple stimulants than those now enumerated have been employed, such as, tickling the parts with a feather, which, according to the statement of Mr. Wardrop, proved beneficial in a case of eighteen months' standing, which recovered in two months. Stinging with nettles was employed by Celsus, and Graefe is said to use the *dolichos pruriens* as an external stimulant applied to the surface, and maintained in apposition with it by means of a bandage. It produces some degree of cutaneous inflammation, but requires frequent renewal.

Among the external stimuli we may mention electricity; the efficacy of this agent in many paralytic cases does not want proof. Lightning has been known to cure paralysis: we extract an anecdote exhibiting this effect of the electric fluid from one of the numbers of the Medico-Chirurgical Review: a vessel on the Atlantic was struck several times with lightning, insomuch that many of the crew were strongly electrified. Among the passengers was a man who had been paralysed in both his inferior limbs for three years. At the time of the electric discharge he lay on his bed, but soon after perceived the return of power to his limbs, and was enabled to rise with perfect use of them. The cure in this case was permanent. A case is related in the Haerlem Transactions, in which a hemiplegic patient recovered the use of his side after a hundred strokes from the *gymnotus electricus*, or electric eel.

Though it must be admitted that electricity is occasionally a successful remedy in palsy, still it has by no means equalled the anticipations at first

entertained respecting it. Its failure may be very well ascribed to a cause which is equally calculated to impair the power of all stimulants over palsied nerves. "Applied in a certain manner," says Dr. Cooke, "electricity is a most powerful stimulant to the nervous system; but as it is also a stimulus to the sanguiferous system, it has often been hurtful in those palsies which depend upon a compression of the brain, and especially when it has been so employed as to act upon the vessels of the head." Great circumspection must be observed, lest in the use of electricity we excite the circulation to such a point as to increase the evil we seek to remedy. Applied as a topical remedy, it will be less apt to produce mischief, and for this purpose the method of *electro-puncture*, already alluded to under the head of Local Palsy, may be resorted to with advantage. The facility afforded of gradually increasing the force of the shock by the employment of the galvanic apparatus, renders galvanism a more safe and suitable agent than electricity; and according to the conclusions of Dr. Bardsley from comparative observations, its efficacy is superior to that of electricity.

But there is a class of internal stimulants which, having a tendency to excite the nervous system so as often to produce convulsive action, have been employed in paralytic cases. Among these we may mention rhus toxicodendron, strychnine, brucine.

The rhus toxicodendron (*poison sumach*) was first introduced by Dr. Alderson, of Hull. A powder from the leaves is given in doses of half a grain three times a day, and its quantity increased to two, three, or four grains, carefully watching its effects. Its most common effect is a twitching or convulsive motion, or a sense of tingling or pricking in the paralytic part. The medicine, like all of this class, does not seem much to be relied upon.

Strychnine and brucine,—the former the active principle of the nux vomica, the latter extracted from the bark of the false angustura, (*brucia antidysenterica,*)—are both remedies of the same class, powerful excitants of the nervous system. Strychnine, however, is much more potent than brucine. Andral ascertained by comparative trials that six grains of brucine were equal in their effects to one grain of impure, or a quarter of a grain of the pure, strychnine: he therefore considers the former a safer medicine than the latter. Both, however, are dangerous and uncertain: dangerous, from the risk of increasing cerebral irritation,—an effect which we have frequently seen; and uncertain, inasmuch as some persons appear more susceptible of their effects than others. Thus, in one individual one-twelfth of a grain of strychnine, produced severe symptoms; and in another the dose was raised to a grain without inconvenience. Andral comes to the conclusion, that in cases where, as if from habit, the paralysis continues after the effusion has been absorbed, the limbs will be improved under the use of strychnine or brucine; that when the brain is still in a disordered state, these medicines have the effect of exciting inflammatory action; but that, in those forms of palsy not dependent on disease of the nervous centres, they are advantageous, as, for instance, in the lead palsy, or that from rheumatism. (Journal de Physiologie, 1823.) Strychnine may be administered in doses of one-twelfth or one-eighth of a grain, gradually and cautiously increased. Brucine may be given in half-grain doses.

The following observations, from Dr. Abercrombie, respecting the administration of stimulants, are well worthy of attention:—"All the remedies of this class must be used with a considerable degree of caution; and perhaps the use of them may be more safe, and may be carried on with a greater degree of activity, if the general system, at the same time, be kept in a very low state by spare living and occasional evacuations. This, I imagine, is always to be considered as an essential part of the treatment, and I cannot agree with some respectable writers, who hold that the diet in paralytic cases ought to be nourishing and restorative. With this precaution, I think it probable that there are many cases of paralysis in which stimulants may be employed with much benefit."

Iodine, in various forms, has been of late years employed in the treatment of palsy. The result of Dr. Manson's (Researches on Iodine, &c.) trials of this medicine are not very encouraging. In scrofulous constitutions, where the paralysis seems immediately dependent on some local development of scrofula, it may be tried with more hope of success than in any other form.

A sudden excitement of the nervous system has been known to carry off the palsy. Thus, a violent fit of mental emotion, anger, fright, have had this effect. The sudden supervention of a fever has likewise removed it: hence Dr. Good recommends as a remedy, in some instances of paralysis, a journey into the hundreds of Essex, or some other marshy district!

Several cases are on record of the spontaneous cure of hemiplegia, as it were by the mere remedial energy of nature. (See Abercrombie, p. 306, et seq.)

3. **Paraplegia.**—It is of importance, for reasons which will presently appear, to decide what is the established acceptation of this term among medical writers. The principal modern writers, as Sauvages, Cullen, Swediaur, Good, (see their Nosological Systems,) Baillie, Cooke, and Rostan, employ the term paraplegia to denote that species of palsy in which the lower half of the body on both sides is paralysed. Much confusion existed among the older writers as to the sense in which they used this term: Hippocrates signifying by it any palsy which was the consequence of apoplexy; Aretæus denoted by it a partial palsy in any situation; Boerhaave and Van Swieten a palsy of all the parts below the neck. Mr. Earle has infringed upon the unanimity of modern writers by endeavouring to revive the definition of Boerhaave and his commentator; for what reason we are at a loss to understand, inasmuch as the etymology (Παρά, vitiose, and πλήσσω, percutio) of the word affords us but little guidance.

We have preferred adhering to the definition of Cullen and others,* as that which is almost universally adopted, and, moreover, because that

* "But there is another form of paralysis, called paraplegia, in which the lower half of the body is more or less impaired in its nervous power."—*Baillie.*

degree of palsy which Mr. Earle employs the term paraplegia to denote, appears to us to come more appropriately under our division of *general paralysis*. When paraplegia is perfect, there is complete loss of the power of motion in the lower limbs, with paralysis of the bladder, rectum, and sphincters; there is also in general a considerable degree of impaired sensation, more, as we have already had occasion to remark, than in any of the other forms of paralysis of motion. Very frequently we find paraplegics more or less affected with spasmodic action in some particular muscles of the lower limbs; sometimes this is confined to the flexor muscles, and we occasionally see a permanent state of flexion of the thighs on the trunk, and the legs on the thighs; sometimes, on the other hand, the extensors are thus spasmodically affected, as in the case of a young man which occurred to the writer, in which there was no power of flexing the lower limbs; but if at the request of the patient they were placed in the state of flexion, (for when in that condition they were more free from uneasiness,) after the lapse of a short interval they were, by short and successive twitchings of the extensor muscles, gradually brought back to the state of extension.

In general there is, along with the palsy of the limbs, paralysis of the bladder and of the sphincters; the former shows itself sometimes by incontinence of urine, but more frequently by retention. All ages are liable to paraplegia, but it occurs more frequently in adults and old persons, and, according to Dr. Baillie, in males than in females.

In the mode of access of paraplegia there is less variety than in that of hemiplegia. The first symptom is generally a derangement of sensation, a sense of numbness in the lower limbs, with impaired power of motion. The weakness of the limbs is further indicated by the patient evincing a tendency to trip when walking, being tired after but a little exertion in that way; complaining of a sense of weight and some degree of pain in the feet and extending up the legs. "The want of power of motion in the limbs, and the inability to preserve the due balance of the body, very much increase, and the person cannot walk without the assistance of one or two sticks, or the aid of some other person, who more or less supports him." (*Baillie*, Trans. Coll. Phys. vol. vi.) The paralysis of the bladder and sphincter next appears, and now the patient is obliged to confine himself to his bed; there is a great tendency to sloughing of the nates, or of any part on which there is prolonged pressure; in some cases a communication has been produced between the rectum and bladder, thus affording the patient a relief from retention by converting it into incontinence of urine. The secretion of the kidneys seems a good deal affected in this complaint; the urine seems prone to calculous deposit, a remark which we believe originated with Dupuytren, who observed that catheters left in the bladders of paraplegics became more quickly encrusted with calculous matter. Sometimes there is a remarkable degree of flatulency of the abdomen, amounting even to tympanitis. The uterus is likewise found to be incapable of its contractions in cases of paraplegia. This fact was observed by M. Brachet of Lyons, who had a patient who became pregnant during the existence of the paraplegia: it was necessary to effect delivery by the forceps. It may be stated that the same physician found, by experiments on animals, that injury to the lumbar portion of the spinal marrow destroyed the contractile power of the uterus.

This form of palsy may depend on disease of the brain or of its membranes, or of the spinal cord or its membranes, or disease of the vertebræ or the uniting ligaments. It was not very long ago supposed that paraplegia resulted only from spinal disease, and Dr. Baillie was the first to call the attention of the profession to its dependence on diseased brain, the spinal cord being perfectly healthy. If diseased brain can produce a palsy of one lower limb, as in hemiplegia, why should not a more extensive or differently situated disease produce palsy of both lower limbs? Were the views of Foville regarding the influence of the corpora striata over the lower extremities established, it is obvious that the effect of simultaneous disease in both would be the production of paraplegia. It must be confessed, however, that the general symptoms of paraplegic palsy chiefly resemble those resulting from spinal disease: the tendency to spasm, the frequent impairment of cutaneous sensibility, the absence, in many instances, of any of those symptoms which so often precede or accompany cerebral disease, are so many circumstances connected with paraplegic which favour the above opinion. Admitting, however, the possibility of the production of paraplegia by cerebral disease alone, we cannot but consider that, as a practical question, it is still *sub judice*, and that chiefly from the too frequent neglect of examining the spinal marrow. Thus we read reports of cases of this affection where post-mortem inspection discloses marked disease of the brain; but from no examination of the spinal marrow having taken place, we can arrive at no satisfactory conclusion. A case of this kind is reported in Dr. Abercrombie's work. The patient was a boy, seven years of age, and before death was blind, epileptic, and paraplegic. Examination after death discovered a firm white tumour, the size of a large bean, lying over the junction of the optic nerves. There was extensive effusion to the amount of twelve ounces in the ventricles, and both hemispheres of the cerebellum were diseased; the left being much indurated, the right reduced to a mass of unhealthy scrofulous suppuration. The spine was not examined.* Who could venture, in the true spirit of philosophy, to state to what cause the paraplegia was attributable in this case?†

Perhaps the greatest difficulty which the practitioner has to encounter in the consideration of a case of paraplegia, is to determine the precise seat of the lesion which gives rise to it. In some cases there are unequivocal signs of spinal dis-

* *Abercrombie*, p. 182. In a case by Mr. Earle, the lower part of the spinal marrow was not examined, yet it is headed "Paraplegia from Disease of Brain." Med Chir. Trans. v. xiii. p. 530.

† See an interesting paper on paraplegia in the Med. and Phys. Journal for June 1827, by Dr. Burder, who considers that those cases of paraplegia which are coincident with cerebral lesion, are caused by the increased *spinal* effusion consequent on that lesion.

ease, such as great tenderness on percussion over a particular portion of the spine; alteration of the form of the spine; projection of one or more vertebræ. Mr. Copeland has adopted a very simple and obviously useful expedient in obscure cases to ascertain the locality of spinal irritation; he takes a sponge dipped in water as hot as can be borne, and passes it down the whole length of the spine; and if there be any irritation confined to a particular spot, the patient will evince it by expressing pain, and wincing as the sponge passes over that region.

The habit of the patient, his previous mode of life, as well as the symptoms immediately preceding the attack of paralysis, will assist the practitioner to discover whether any cerebral affection is complicated with the spinal disease; thus in some instances, as Mr. Earle remarks, there is an impaired state of some of the external senses, accompanied with vertigo, a sense of weight on the head, and a general disturbance of the cerebral functions; in some there is likewise derangement of one or more of the mental faculties. In such cases there can be little doubt of at least *the complication* of cerebral disorder. "But," as Mr. Earle adds, "it is in slighter and more chronic cases that it is often difficult to form a correct opinion; yet to establish a correct diagnosis in such cases is of the utmost importance both with respect to the probable termination of the case and with reference to the proper treatment to be adopted, that we may not subject the individuals to useless suffering from the application of caustic issues and setons to the spine, and the disappointment which would follow." To obviate this difficulty, Mr. Earle has proposed an expedient which we shall give in his own words: "It is well known that when a nerve is stimulated or injured in any part of its course, the painful sensation is referred by the percipient mind to the sentient extremity of such nerve; the familiar instance of the pain referred to the extremity of an amputated limb may be adduced in proof of this. The exact reverse of this takes place when there is a partial paralysis arising from morbid affection of the cerebral organs. Here the centre of the sensorial functions being impaired, it appears to be incapable of transmitting its influence to the extreme parts of the body; in such cases, if the nerves supplying the limbs be irritated, *they will convey the impression of such injury only part of the distance down the limb, about as far as the commencement of the paralytic affection.* I have repeatedly examined cases of paraplegia from affection of the spine, and in no one instance have met with the same phenomenon, which I have therefore been induced to consider as diagnostic of the paralytic affection being dependent on disease of the brain or its membranes; which opinion has in several instances been confirmed by examinations after death, in which both brain and spinal marrow have been carefully investigated." It is hardly necessary to mention that paraplegia is a frequent result of concussion and other spinal injuries.

Treatment of Paraplegia.—As topical remedies are chiefly applicable in this form of palsy, it must be obvious of what importance it is to ascertain to what region they may be most advantageously applied. Cupping and leeching are, in the generality of cases, primarily indicated. Counter-irritation by blisters, issues, setons, moxas, &c. may then be had recourse to. Purgatives are to be administered as they may appear necessary; and Dr. Baillie's mode of treatment is well calculated to be serviceable; he directed a grain of calomel, or five grains of the pilula hydrargyri, with one grain of dried squills, to be taken every night for many weeks; these were followed by purgatives.

The same treatment of the palsied limbs may be adopted here as that alluded to under the head of hemiplegia. The palsy of the bladder will require the introduction of the catheter, and we would merely allude to the necessity of using pressure above the pelvis to ensure the complete expulsion of the urine.

Certain mineral poisons, viz. mercury, lead, and arsenic, give rise, when received to a great extent into the system, to a form of palsy which Cullen has denominated *venenata*. The palsy resulting from mercury and lead has already been so fully treated of that we think it needless to allude further to it here. (See Artisans, Diseases of, and Colica Pictonum.)

Palsy has, in some cases, followed the use of arsenic, chiefly where it had been taken or administered as a poison. In some of the cases related by Orfila, the palsy was not extensive, and appeared a short time before death. In a young man whose case is related in the Medical and Physical Journal, there was paralysis of the four extremities, which continued for some time, and ultimately proved fatal.

Paralysis Agitans.—[*Shaking Palsy.*]—The peculiar affection thus denominated by Mr. Parkinson is the *scelotyrbe festinans* of Sauvages, and from the peculiarity of the patient's gait has been called by Dr. Good synclonus ballismus (βαλλίζω, *tripudio.*)

Mr. Parkinson's description of the disease is the best we possess; we therefore subjoin it. "So imperceptible is the approach of this malady, that the precise period of its commencement is seldom recollected by the patient. A slight sense of weakness with a proneness to trembling, sometimes in the head, but most commonly in the hands or arms, are the first symptoms noticed. These affections gradually increase, and at the period perhaps of twelve months from their first being observed, the patient, particularly while walking, bends himself forward. Soon after this his legs suffer similar agitations and loss of power with the hands and arms. As the disease advances, the limbs become less and less capable of executing the dictates of the will, while the unhappy sufferer seldom experiences even a few minutes' suspension of the tremulous agitation; and should it be stopped in one limb by a sudden change of posture, it soon makes its appearance in another. Walking, as it diverts his attention from unpleasant reflections, is a mode of exercise to which the patient is in general very partial. Of this temporary mitigation of suffering, however, he is now deprived. When he attempts to advance, he is thrown on the toes and forepart of his feet, and impelled unwillingly to adopt a running pace, being in danger of falling on his

face at every step. In the more advanced stage of the disease, the tremulous motions of the limbs occur during sleep, and augment in violence till they awake the patient in much agitation and alarm. The power of conveying the food to the mouth is impeded, so that he must be fed by others. The torpid bowels require stimulating medicines to excite them into action. Mechanical aid is often necessary to remove the fæces from the rectum. The trunk is permanently bowed; muscular power diminished; mastication and deglutition are difficult, and the saliva constantly dribbles from the mouth. The agitation now becomes more vehement and constant; and when exhausted nature seizes a small portion of sleep, its violence is such as to shake the whole room. The chin is almost immovably bent down upon the sternum; the power of articulation is lost; the urine and fæces are discharged involuntarily, and coma with slight delirium closes the scene." (Parkinson's Essay on the Shaking Palsy. London, 1817.)

But few cases of this disease are recorded: it possesses many points of similarity to chorea, or to the palsy from mercury, which has been better termed *tremblement mercuriel*. It is therefore to be distinguished from these diseases as well as from the trembling which succeeds the abuse of spirituous liquors; that which proceeds from the immoderate use of tea or coffee; or that which appears to be dependent on old age. In these cases the agitation ceases if the trembling limb be supported, and none of its muscles called into action; whereas, in the real shaking palsy, the reverse takes place; the agitation continues in full force whilst the limb is at rest and unemployed, and even is sometimes diminished by calling the muscles into employment. To this we may add the peculiarity of gait evinced here; "*the patient, when he attempts to walk, being impelled unwillingly to adopt a running pace*," —a symptom which we would be disposed to consider as pathognomonic.

All is conjecture respecting the anatomical condition of the nervous centres in this disease: the symptoms, however, seem strongly to favour the opinion of Mr. Parkinson, that there is spinal disease, and in the cervical portion of the spinal marrow.

The treatment consists in the adoption of the same measures which are applicable in all forms of palsy dependent on spinal diseases.

R. B. Todd.

PARAPLEGIA. See Paralysis.

PAROTITIS, (from παρωτις, the parotid gland,) inflammation of the parotid gland, *mumps*. Inflammation of the parotid gland is an occurrence which may be the effect of the common causes of inflammation generally, in healthy persons, as of exposure to cold or local injury; or it may be secondary, and consequent to a cachectic state of the body or already existing disease, as in strumous subjects, and as it takes place occasionally in a subacute form at the termination of fevers, to which it has sometimes appeared to be critical. Parotitis is now and then observed to follow the inflammatory eruptive diseases, as measles, small-pox, and scarlatina; and occasionally to come on as if from the absorption of acrid matter from diseases of the surrounding parts, as eruptions or excoriations. Lastly, parotitis presents itself as a peculiar and probably a specific disease, characterised by the duration of its inflammatory stage, and originating from no manifest exciting cause, except contagion. As it occurs under all but the last-mentioned circumstances, the affection corresponds to the *parotis* of some of the ancient writers, and to the *phlegmone parotidæa* of Mason Good: the exception constitutes the *empresma parotitis* of the same nosologist, and the cynanche parotidæa of Cullen, its more general nosological appellation at the present period.

Parotitis, from whatever cause it may arise, is characterized by tumefaction of the parotid gland, recognisable by the eye and hand of the examiner, together with local pain increased by and rendering difficult the natural movements of the lower jaw, and giving rise to febrile symptoms more or less severe. The modifications of it which seem to arise from various causes, and *not* from contagion, we shall refer to under the term simple parotitis; that which has the more peculiar character, commonly known by the name of cynanche parotidæa, we propose to treat of afterwards, under that name, as a distinct disease.

1. *Simple Parotitis* presents, in most of its circumstances, phenomena similar to those of inflammation in other parts which have the same relative approximation to the surface of the body, namely, local pain, tumefaction, and increased heat, and, as it advances, redness of the superjacent integuments; added to these, there is occasionally a sense of throbbing about the parts, with headach and other cerebral disturbance, and occasionally even difficulty of respiration and deglutition. The degree of fever which accompanies it is proportionate to the extent of the local affection and the irritability of the subject. At an uncertain period, simple parotitis terminates in resolution, with subsidence of the febrile symptoms, or goes on to suppuration or abscess and ulceration, and may even end, although it very rarely does so, in gangrene and death.

Parotitis is often so transient and little distressing to the patient as to yield to the mere promotion of warmth to the part by covering it with flannel or any other additional wrapper; and it may be well to remark here that warm applications to the angle of the jaw, in all inflammatory swellings of the parotid gland, contribute much more to the mitigation of pain and other consequent symptoms than the cold epithems usually found to give relief in inflammation of other parts. When parotitis is more severe, detraction of blood from the region of the inflamed gland will be further necessary; to be followed up by constitutional treatment of the antiphlogistic kind, proportioned to the general effects of the local disease. If, nevertheless, suppuration should not be prevented, an early outlet should be made for the contents of the abscess, and the treatment of this and every other stage of the disease pursued on the principles laid down in the article Inflammation.

The subacute inflammation of the parotid gland, which is occasionally found in complica-

tion with scrofula and other diseases, is, in fact, a manifestation of them, and pertains to their discussion in other parts of this work. When consequent to acute or eruptive fevers, the primary inflammatory stage is rarely if ever to be recognised, and an abscess of the gland proclaims that it has existed. An early evacuation of the contained pus will be the direct medium of relief, and the treatment of debility consequent to such diseases, of which it is generally an indication, the method to be pursued for the further restoration of health.

When parotitis is a consequence of any particular state or disease of the adjacent parts, the removal of its cause must be the first object of attention. Leeches, however, applied to the region of the enlarged gland will give relief, and their repeated use may be necessary to counteract the continued operation of an irritant, the removal of which perhaps cannot be immediately effected.

2. *Cynanche parotidæa* is that species of parotitis commonly known in this country by the name of *mumps;* in Scotland called *branks;* and in France *oreillons* and *ourles*. It is almost universally admitted to be contagious; it is often endemic, and sometimes epidemic. It commences with the local symptoms already mentioned as common to parotitis in general, but the tumefaction, which is at first distinct, soon extends to the maxillary glands, (if the latter be not synchronously affected,) over a considerable part of the throat; the disease is frequently developed in the glands of both sides, but sometimes only of one; febrile symptoms, varying in degree, but usually slight, are also present, and increase as the swelling advances, until about the fourth day, when both the local and constitutional disorder begin to subside; and within as many, or sometimes a few more, they entirely disappear. As the tumefaction diminishes, it not unfrequently happens that the testicles in the male sex, and the mammary glands in females, begin to increase in size, become hard and somewhat painful, but in this country soon again recover their former state. Experience has proved that this local determination is a favourable omen, for its non-occurrence as well as its expulsion have been frequently succeeded by inflammation of some other organ, generally the brain or its membranes, and even death has been the unfortunate issue.

In cynanche parotidæa the inflammation of the gland rarely if ever terminates in suppuration, but almost always manifests a tendency to resolution, on or about the fourth day of its progress.

When the inflammation has been confined to the glands on one side, the translation above noticed has generally also been evinced in the corresponding testis or breast.

A large majority of persons have passed through life without ever having suffered from this disease, and it is not common to find that it has been experienced a second time. We are not aware that its prevalence is peculiar to either sex, but children are generally the subjects of it, and more frequently those of a strumous diathesis: in such subjects, an occasional and apparently consequential occurrence is a more decided development of struma in the glands which have been the seat of vascular excitement. At sea, it has occasionally happened that cynanche parotidæa has attacked a number of sailors in the same vessel, when the cause of its first appearance has not been very evident; for, although besides contagion, exposure to cold and humidity have been commonly considered its exciting causes, it has occasionally arisen without any evident reason to suspect that it has been the effect of either.

Treatment.—Common observation has taught that cynanche parotidæa might in most instances be safely allowed to proceed without other care than that of guarding against exposure to cold of the general surface of the body, but particularly of the local swelling; by the abstinence from food and drink of a stimulating quality, with the occasional exhibition of gentle laxatives, purgatives having sometimes appeared to occasion a metastasis of the inflammation to another organ. To promote local warmth, the usual application of flannel round the neck and jaws is congenial alike to the feelings of the patient, and calculated to counteract the proneness to metastasis of the inflammatory action. When one or both of the mammary glands or testes are only slightly affected, a continuation of the same plan of treatment will generally be found adequate in aid of the natural actions of the body; but if the inflammation should be excessive, either in the original or consecutive stage of the disease, the antiphlogistic line of treatment must be more rigidly adhered to; topical detraction of blood by leeches, or, when the testis is the organ requiring relief, by several small punctures, with a lancet, of the superficial vessels of the scrotum, must be adopted, and even general bloodletting in further relief of the system. The depleting plan should be extended to the more active saline aperients, and to diaphoretic and diuretic medicines of the same class with antimonials, to be selected and varied on the general principles of therapeutics, according to the particular exigencies of the individual subject of the disease.

The well-established fact in pathology, of the tendency to metastasis of inflammation from its original seat to some other organ in cynanche parotidæa, renders it an important axiom that cold applications, whether to the parotid, maxillary, or mammary glands, or to the testes, should be carefully avoided, at least whilst the progressive steps evince the peculiar character of this disease. The secondary as well as original inflammation, when confined to these glands, will be soonest relieved by hot fomentations and the continued application of flannel: when leeches have been applied, as before advised, the same object will be further promoted by enveloping the part in a bread-and-water poultice, which should be renewed at intervals of six hours. Observance of the horizontal posture, the warmth of bed, and a suspending bandage, when the testis is enlarged and painful, will also be important auxiliaries. If, unfortunately, a metastasis should occur, and the brain or its membranes (which under such circumstances is most common), or any other structure become the seat of the vicarious inflammation, the new form of disease must be the immediate object of attention, requiring precisely the same treatment as if it were wholly unconnected with its precursor, whilst at the same time

an attempt should be made to divert the inflammatory action to the organ from which it has receded, by the immediate application to the latter of hot fomentations, and subsequently by local irritants: blisters have been usually recommended for this purpose, but as the probabilities of success (at all events very slight), it is reasonable to suppose, would diminish in proportion to the length of time from which the inflammation had left the particular organ, a sinapism, we conceive, on account of its quicker action, would be preferable. [It may admit, moreover, of doubt, whether the irritation produced by a blister or sinapism, may not also be transferred to the seat of the metastasis, and add to the irritation there.]

In advanced life, Dr. Mason Good observes, cynanche parotidæa is apt to run into a chronic form, accompanied with symptoms formidable in their nature. This is more especially apt to take place, he adds, in females when menstruation is on the point of ceasing, and the general action of the system labours under some disturbance. The tumour should, if possible, be carried off by leeches and cooling repellents, as he further advises, urging as a reason that if it proceed to suppuration, which it tends to, though very slowly, the ulcer rarely heals, usually degenerating into a foul offensive sore that sinks deeper and spreads wider, resisting all medical treatment, and at length destroying the patient. Vomits, frequently repeated, he continues, have in this case been found highly serviceable, and those of the antimonial preparations rather than ipecacuanha, from their maintaining a longer action, and determining more effectually to the surface, or rather to the excernents generally.

WILLIAM KERR.

[PARTURIENTS; from *parturio*, 'I bring forth.' 'Substances that promote the parturient energy' are thus designated by the writer. The term has been objected to, (*Brit. & For. Med. Rev.* Jan. 1844, p. 244,) and is objectionable; but it is not so easy to propose one more appropriate. *Abortives, Amblotics, Phthorics, Apophthorics,* and *Ectrotics,* used at times, are certainly not less objectionable. Fifty years ago, no one, in this country, would have ventured to affirm, that the lists of the materia medica comprised any agents possessed of the virtues ascribed to parturients. In Germany, indeed, ergot has long been regarded in this light, as its old German names, *mutterkorn,* ('womb-grain,') and *gebärpulver,* ('parturient powder') sufficiently testify. Within the period specified, ergot has been brought to the notice of the profession here, and elsewhere, and has received so many testimonials in its favour as to cause its admission into every work on materia medica. In no country has it been more employed than in the United States, and in none has it so many supporters. Yet there are many who, from their experience, are not satisfied, that it exerts the power over the gravid uterus, that has been ascribed to it. It must be admitted, as the writer has elsewhere remarked, (*General Therapeutics and Materia Medica*, i. 422, Philad. 1843,) that no cases could present themselves, in which it is more difficult to trace accurately the relation between cause and effect. Every one who has practised extensively in obstetrics must have observed, that the parturient efforts occasionally flag, and, indeed, are wholly suspended; yet they recur, and the labour proceeds rapidly to a favourable termination; and if in any such case a remedy, presumed to be parturient, were administered during the period of the cessation of pain, the recurrence of the pain in this sudden manner could hardly fail to be ascribed to the administration of the presumed parturient. Let the obstetrical practitioner, who has never had recourse to any such agent, call to mind how few the cases are in which delivery has had to be aided, in consequence of the *total* cessation of the pains, and how common it is to meet with a partial or temporary cessation; and he will see, that the absolute necessity for the use of a parturient is not a common occurrence.

But if hesitation be indulged in allowing the ergot any special powers over the uterus, there can be none in denying such powers to other reputed parturients. They are all indirect agents, and act only upon the ovum through the mother, endangering her life, as well as that of the new being. The drugs and agencies employed with the view of inducing abortion are of the most powerful kind,—emetics, drastic cathartics, acro-narcotic poisons, &c., &c. Many of the German writers, indeed, (Schroff, *Taschenbuch der Arzneimittellehre, u. s. w.* s. 108,) ascribe to borax a specific influence over the uterus by which it is supposed to favour the catamenial secretion, the pains of parturition, and the lochial discharge, when their failure is dependent upon inactivity of the organ. Dr. Copland (*Dictionary of Practical Medicine*, art. ABORTION) recommends it combined with ergot, in cases of abortion, when the embryo only is expelled—the appendages being retained, and the hemorrhage great.

ROBLEY DUNGLISON.]

PELLAGRA, or PELAGRA. This is the name of a disease in which a morbid condition of the skin is a prominent symptom, very prevalent amongst, if not exclusively peculiar to, the peasantry of the northern states of Italy: the word pellagra is obviously a compound from the Latin *pellis*, the skin, and *agria*, "scabies fera," signifying an inveterate eruption.

The earliest account given of pellagra is from the pen of Francis Frapoli, a physician of Milan, and was published in the year 1771; since which period it has been the subject of a great deal of discussion and controversy amongst the Italian practitioners and medical writers. Of our own countrymen, Dr. Holland (so far as we have been able to ascertain) is the first whose description of the disease was founded on personal observation; and excepting a recent sketch of its prominent features by Dr. James Johnson, his paper is the only one in our literature to which the desirable distinction of originality can be attached: it has not, however, escaped the attention of Parr and Hooper, (Medical Dictionaries,) and has been noticed by Good under the title of Elephantiasis Italica, and by Alibert under that of Ichthyosis Pellagra. Dr. Holland has expressed himself decidedly of opinion that it should be classed among the impetigines, but has remarked its resemblance to an inveterate degree of Psoriasis or

lepra vulgaris, admitting also that it has some affinity to ichthyosis. [See, also, L. V. Lagneau, art. Pellagre, in *Dict. de Méd.* xxiii. 373, Paris 1841; and art. Pellagra, in *Encyclopädisches Wörterb. der Medicinisch. Wissenschaft.* xxvi. 444, Berlin, 1841.]

General observation has determined that there is considerable variability in the symptoms of pellagra, and that they are often complicated with other forms of disease; a fact which, with the circumstances of the protracted period of its entire development as well as of its intermitting appearance and remissions, may in a great measure account for the conflicting opinions concerning its nature and history. The poor are almost exclusively its victims; and of these chiefly the peasantry and such as are occupied in agriculture. In the ordinary form of its occurrence, according to Dr. Holland,* it first appears as a local disease of the skin, preceded, however, occasionally by languor, debility, and other indications of a general cachectic state of the body. The local symptoms very generally show themselves, in the first instance, early in the spring, at the period when the midday heat is rapidly increasing, and when the peasants are most actively engaged in their labours in the fields. The patient perceives on the back of his hands, on his feet, and sometimes, but more rarely, on other parts of the body exposed to the sun, certain red spots or blotches, which gradually extend themselves, with a slight elevation of the cuticle, and a shining surface, not unlike that of lepra in its early stage. The colour of this eruption is a somewhat more obscure and dusky red than that of erysipelas: it is attended with no other uneasy sensation than a slight pricking or itching, and some tension in the part. After a short continuance in this state, small tubercles are frequently observed to arise on the inflamed surface; the skin almost always becomes dry and scaly, forming rough patches, which are excoriated and divided by furrows and rhagades. Desquamation gradually takes place, which, though it leaves behind a shining unhealthy surface in the parts affected, yet in the first year of the disease is rarely followed by a repetition of the appearances just described. Towards the close of summer, or occasionally still earlier, the skin has resumed its natural appearance; and but that the further progress of the disease is familiar to every inhabitant of the country, the patient might be led to flatter himself that the evil was gone by, and that there was no particular reason to dread its recurrence.

With this local affection are connected, even in the first period of the disease, certain general symptoms, important inasmuch as they indicate the constitutional nature of the malady; namely, debility of the whole body; vague and irregular pains of the trunk and limbs, but especially following the track of the spine and dorsal muscles; headach with occasional vertigo; irregular appetite, and general depression of spirits. The bowels are for the most part lax, and usually continue so in the further course of the disease. There are no febrile symptoms, and in females the menstruation is generally continued without irregularity.

The remission which the patient obtains during the autumn and winter of the first year is almost universally followed by a recurrence of his symptoms, in the ensuing spring, under a more severe form, and with much greater disorder of the constitution. The cutaneous disorder returns and spreads itself more extensively, but, as before, affecting chiefly the hands, neck, feet, and other exposed parts of the body. The skin becomes callous and deeply furrowed; and large rhagades show themselves, especially among the articulations of the fingers. The debility is greatly increased, frequently depriving the patient of all power of pursuing his active labours, and rendering him peculiarly susceptible of all changes of temperature. Partial sweats break out without any obvious cause. All the nervous symptoms of the first year are renewed in a more severe degree; there is a general tendency to cramp and spasmodic affections; the mind begins to suffer under the disorder, and the feeling of anxiety and despondence is very strongly marked. The *libido inexplebilis*, mentioned by some writers as one of the characteristic symptoms of pellagra, did not come under Dr. Holland's notice, and he is disposed to believe that it has been so considered from the credulity common upon this topic, or to a desire of associating the disease more closely with the leprosy as described by ancient writers. The other symptoms already noticed make progress as the heat of summer advances, and with greatest rapidity in those patients who are much exposed to the sun. As in the preceding year, they begin to decline towards the middle or end of autumn, but the remission, as well of the local affection as of the general disorder is much less complete than before, and the patient continues to suffer during the winter from the debility and other effects consequent upon the disease.

In the third year, every symptom is renewed at an earlier period, and in an aggravated degree. The constitutional malady shows itself under a variety of forms, some of the symptoms having a considerable analogy to those of scorbutus; all of them indicating a general cachexy, and more particularly a lesion of all the voluntary functions. The debility now becomes extreme: the patient is scarcely able to support himself; and the limbs, besides their feebleness, are affected with pains, which still further impede the power of motion. The diarrhœa continues, and tends, of course, to augment the patient's weakness. Frequently a dysenteric state comes on in the latter stages. The breath is generally fetid, and the odour of the perspiration often extremely offensive. The appetite and digestion are irregular, yet, on the whole, perhaps less affected than most of the other functions. Dropsical effusions are now apt to supervene,—occasionally ascites, but more commonly anasarca. Vertigo, *tinnitus aurium*, and double vision are almost universally concomitants of this stage of the disorder, and all the senses become exceedingly impaired. Some spasmodic affections are very general, and these not unfrequently of an epileptic character.

Connected with these latter symptoms is the effect which the pellagra produces upon the minds

* See his valuable paper on the subject, published in the eighth volume of the London Medico-Chirurgical Transactions.

of the sufferers, which effect forms one of the most striking circumstances in the history of the disease. The anxiety, watchfulness, and moral depression of the patient are rapidly augmented. The unhappy objects seem under the influence of an invincible despondency: they seek to be alone; scarcely answer the questions put to them, and often shed tears without any obvious cause. Their intellectual faculties and senses become alike impaired, and the progress of the disease, where it does not carry them off from debility and exhaustion of the vital powers, generally leaves them incurable idiots, or produces maniacal affections, which terminate eventually in the same state. "In demonstration of this tendency of the disease, I may mention the fact," says Dr. Holland, "that at the time I visited the Lunatic Hospital, at Milan, there were nearly five hundred patients, of both sexes, confined there, of which number more than one-third were pellagrosi, people brought thither by the termination of their disorder either in idiocy or mania. Even this statement gives little adequate idea of the nature of its ravages. The public hospitals of the country are far from sufficient to receive the vast number of persons affected with the pellagra; and the greater proportion perish in their own habitations, or linger, wretched spectacles of fatuity and decay. Where debility, as generally happens, is the cause of death, it manifests itself in the latter stage with the usual concomitants of colliquative diarrhœa, spasmodic affections, and coma, and produces a degree of emaciation scarcely to be surpassed in any other disease."

"Though, for the sake of brevity," continues Dr. Holland, "I have described this train of symptoms as going on from the third year, I may remark that the pellagra is generally of longer duration, and that other intermissions usually occur in its progress, giving the patient a certain relief in the degree of his sufferings, though little hope as to the issue of the disease. In some instances, the cutaneous affection forms the principal indication of the complaint for several successive years, being renewed every spring, and disappearing again every autumn. In other cases, where it has been found possible to remove the patient to a new situation and mode of life, the disease is still further arrested in its progress. It rarely happens, however, that these means can be practically adopted, and the constitutional malady is generally so far established in the third or fourth year, that little hope remains of benefiting the patient either by medicine or change in the mode of life."

[At times, according to a recent writer, (L. V. Lagneau, *op. cit.* xxiii. 373,) the insanity assumes the religious form, with tendency to suicide, degenerating occasionally into homicidal monomania, which is directed by preference to children. Numerous examinations of the dead, made in the Hospital Saint Ambrosia, at Milan, by MM. Panceri,—father and son,—assisted by M. Brière de Boismont, (*Ibid.* or *De la Pellagre et de la Folie Pellagreuse*, Paris, 1834,) established most incontestably that these mental aberrations were owing to chronic meningitis, often extending into the vertebral canal. M. Brière de Boismont likewise found the digestive organs of all manifestly diseased, and presenting evident traces of inflammation.]

To enumerate all the symptoms which the Italian writers have attached to pellagra would, in fact, involve a description of several diseases with which it is complicated: it appears, however, that such complications are characteristic of this peculiar malady, and equally so their occurrence under several varieties of form. At different periods, in the same individuals, the morbid condition of the skin has exhibited the appearance of erysipelas, lepra, psoriasis, elephantiasis, and ichthyosis, and of such as are usually termed constitutional disorders, in which it appears to merge: scorbutus, tetanus in its varied forms, chorea, epilepsy, convulsions, dropsies, melancholia, mania, and marasmus, form a condensed list. "It is on this account," Dr. Johnson has observed, "that we see written over the beds in the Milan Hospital the various diseases to which pellagra forms the adjective, as atrophia pellagrina, phthisis pellagrina, hydrops pellagrinus, paralysis pellagrina, mania pellagrina, &c." (Change of Air, or the Pursuit of Health, by James Johnson, M.D. p. 75.) Jansen, one of the most esteemed authors on this subject, states that the cutaneous affection sometimes disappears, but without any mitigation in the other symptoms, and that a person accustomed to see this disease would at once recognise it by the peculiar odour of the perspiration the patients are often bedewed with, compared by him to the smell of mouldy bread. In the advanced stage, the victim of pellagra (the *mal de misère*, as it has been emphatically called by Vaccari,) experiences, in an extreme degree, the effects of irritation in all the mucous surfaces, whilst at the same time the sensibility of the nervous system seems to be infinitely increased. The whole mouth becomes painful, tense, and phlogosed; the palate cleft; the gums swelled, fungous, and bloody; the tongue dry and blackish, and covered with a muddy coating: the teeth blacken and fall out; aphthous ulcerations are not uncommon, and the saliva, which is extremely salt, is frequently secreted in such a quantity, particularly in the morning, as to constitute complete ptyalism: the voice is sometimes so changed as not to be recognisable, and, as may readily be imagined, the thirst is excessive; the latter, however, is the only constant and invariable one of this group of symptoms. As the disease proceeds, diarrhœa becomes uncontrollable, and prior to the fatal issue the emaciation is excessive; but sometimes the patient is said to have the appearance of a mummy. Nervous sensations of a very distressing and peculiar kind also accompany the latter stage; they have been described as a sense of burning heat of the head and spine, radiating to the other parts of the body, and extending particularly to the palms of the hands and to the soles of the feet; occasionally as if an electric spark or flash of fire issued from the brain, and darted through the eyes, ears, and nostrils; all kinds of imagined noises distract the unhappy sufferer; saws, grindstones, mills, hammers, bells, the chirping of birds, and buzz of insects, at one time or another, appear to assail his ears; and thus deprived of sleep or rest, in the summit of despair, it not unfrequently happens that suicide is resorted to; an act which (as if

the means were indicated by some physical association) is often accomplished by drowning, so often as to have induced Strambi to distinguish this particular hallucination by the title of hydromania. (Dict. des Sciences Méd. art. *Pellagra.*)

The consideration of pellagra has been encumbered with a variety of discordant and trivial distinctions. Frapolli, for instance, has divided it into the incipient, the confirmed, and the incurable; Gherrardini into slight, severe, and desperate; Soler into the dry and moist, from some supposed difference in the disorder, according as it appears in dry and elevated situations, or on the flat and moist surface of the plains; and Titius into the latent and manifest, in conformity with the presence or absence of the eruption, the latter being a peculiarity in the manifestation of the disease, but attested by Italian authorities of respectability, amongst whom are Cevri and Zanetti.

It appears that the knowledge of the nature of pellagra has been as yet but little extended by pathological investigation. "In some patients," says Dr. Holland, "the liver, in others the spleen, has been found enlarged and indurated; marks of disease are also occasionally seen in the intestines and mesenteric glands, but these appearances are by no means constant, and may more reasonably be considered as effects than causes of the disease."

Dr. Johnson, in his notice of some cases of mania pellagrina, collected from the great hospital at Milan by M. Brière de Boismont, who visited Italy in 1830, has included the following remarks on the pathology of the disease by that writer: "there is a collection of yellowish serum between the membranes and in the cavities of the brain; congestion of the vessels of the pia mater, plexus choroides, and of the cerebral substance; suppuration and hardening of the brain itself; inflammation of the spinal chord and of its membranes, accumulation of serum in the pleural cavities; inflammation and abscesses of the lungs; ulcers of the trachea; dropsy of the pericardium and of the abdomen; chronic peritonitis; ulceration of the stomach and intestines; hypertrophied tubercles, and scirrhus of the liver, &c." (Medico-Chirurgical Review, Jan. 1833.)

The period at which pellagra first made its appearance, is a point that has been much disputed by the Italian and German physicians, without any satisfactory conclusion. According to Moscati, a Milanese of great repute in science, and some other writers, it has not been known in Lombardy more than between sixty and seventy years. Allioni, who has attempted to estimate the various opinions on the subject, dates its rise in the year 1715, though the attention of the Milanese physicians was not drawn to it until 1740. Strambi, who was appointed by Joseph II. the director of an hospital established at Lagnano, near Milan, for the reception of pellagrosi, had the best opportunities of gaining information on the subject. In his treatises on the pellagra, published in three successive years, from 1784 to 1787, he mentions the fact of his having seen many pellagrosi in the hospital, who gave him distinct assurances of their fathers and grandfathers having had the disorder, and from some particular instances he thinks himself entitled to believe that the pellagra must have been known in Lombardy sixty or seventy years before the time when he wrote. Frapolli contends also for its antiquity, but it may be questioned whether his opinion does not rest on the mere analogy of a name, it having been formed from the circumstance of a minute in the journal of the Milan Hospital, dated the 6th of March, 1578, which provides for the reception of patients attacked with the disease known at that time under the name of *pellarella.*

The pellagra, as an endemic disease, prevails chiefly in the provinces of Lombardy, lying between the Alps and the Po. This country may be briefly described as a vast surface of alluvial plain, little elevated above the sea; but rising on its northern side into chains of hills, which intermediately connect it with the Swiss and Tyrolese Alps. From the long, narrow, and profound lakes among those hills the numerous rivers issue, which, flowing southwards to the Po, and giving their waters into a number of artificial channels for the purpose of irrigation, maintain that extraordinary fertility of soil for which the plains of Lombardy have long been celebrated. The principal objects of cultivation on these plains, besides the vineyards extensively spread over their surface, are maize, rice, and millet. In some districts, and particularly between the rivers Adda and Tercino, the pastures are extensive, and yield a considerable produce of milk, from which the Parmesan cheeses are made. The hilly country, just noticed, on the northern side of Lombardy, is less productive, and cultivated on a more limited scale. The valleys, however, intervening among these hills are of great fertility, yield a considerable quantity of grain, and much wine from the numerous vineyards to which they give shelter.

The district which appears to have suffered most from the ravages of the pellagra, is that which formerly constituted the duchy of Milan, and particularly the Alta Milanese, or that portion of country lying up towards the hills between the Lago Maggiore and the Lago di Como. It was in this part of Lombardy that the disease first became an object of medical attention; and some time elapsed before it was described as appearing in the Venetian provinces, and near the shores of the Adriatic sea. (Medico-Chirurg. Transactions, vol. viii. p. 320.)

The propagation of pellagra has by some been referred to contagion; facts and authority, however, preponderate greatly against this opinion. Its hereditary tendency is proved by its frequent appearance at the earliest period of life, as attested by Dr. Sacco, of Milan, who, in the capacity of Director of the Vaccine Establishment, has had the best opportunities of observation. It has, moreover, been generally remarked that the disease is continued in succession through families. Conflicting accounts are given of the sex in which it most prevails, but there is ample reason to conclude that the discrepancy has arisen from the occupations of the men and women in different districts being reversed, and not from any physical peculiarities in the conformation of either.

In reference to the remote causes, the most important facts in evidence undoubtedly are, the limited period during which the disease appears

to have existed in the country, its being confined almost exclusively to the lower classes, and its rare appearance in the towns or cities of Lombardy. The climate is obviously not the cause concerned; since this, as far as it is known, has been unchanged for a much longer period than that which includes the history of pellagra; or had it been changed, it would have affected alike both the higher and lower classes of the population. The same objection may be made to the opinion that any circumstances of mere locality are concerned in producing the disease. It may possibly be true that the plains of Lombardy are more frequently and irregularly flooded than formerly, and that the general surface is more marshy and unwholesome; but this does little to explain the causes of a disorder which is chiefly prevalent in the higher lands, where such changes have not equally taken place.

The point, then, to which we are almost necessarily conducted, is the mode of life and subsistence among the peasantry: this, it appears, is as wretched as the soil is productive; an evil which has been progressively increasing for more than the last half century, and is probably the result of devastation from repeated wars, political changes, and the consequent heavy taxes and imposts, combined with a decaying commerce and bad arrangement between the landlords and cultivators of the soil.

The ordinary diet of these people consists chiefly of maize prepared in different ways, of rice, millet, beans, and some other articles of vegetable food. Their bread, which is principally made from maize, is for the most part of bad quality, ill fermented, and not unfrequently deficient in salt. Animal food rarely forms a part of their diet; and though living on a soil which produces wine, their poverty almost precludes the use of it, even when sickness and debility render it most needful. The same condition of poverty is evident in their clothing, in their habitations, and in the want of all the minor necessaries and comforts of life. By several of the Italian physicians, the common use of maize has been considered a specific cause of this peculiar disorder. Dr. Holland controverts this opinion by the results of his personal observation with regard to the peasantry in the northern parts of Greece, who, though subsisting chiefly on the same kind of grain, are wholly free from the disease, as is also observed in the south-western parts of Europe, where the same diet is as generally in use among the lower classes; and, with the exception of a disease occurring in the Asturias, (the elephantiasis Asturiensis of Mason Good), Dr. Holland further states that he does not know of its existence in Spain or Portugal, where the maize is very extensively used. Rice has also been supposed to be specifically productive of the disease, but it must be acknowledged that facts by no means warrant the supposition. One circumstance which seems to deserve a prominent place in the consideration of this part of the subject is, the first appearance of the symptoms in the spring of the year, their partial disappearance in the autumn, their renewal in the ensuing spring, and the continuance of this alteration for successive years, whenever the disease is protracted thus long without reaching its latter stages. This chain of phenomena has led Albera, Frapolli, and other Italian writers, to refer the origin of the disease to the frequent exposure of various parts of the body to the action of the sun's heat, which, it seems probable, is an exciting cause of the cutaneous and some other of the symptoms; but that it is not the fons et origo mali is proved by the circumstance of the peasantry of other parts of Italy and of tropical countries being subjected to more intense exposure of the same kind without corresponding results. That such insolation, moreover, is not the only exciting cause, has been proved by the fact adduced by Strambi, that the cutaneous eruption may be prevented by avoiding exposure to the sun, whilst the other symptoms proceed in their usual course. There is also reason to expect that the incipient stage of the disease would, if induced by this cause, be common when the sun's heat was most intense, a circumstance contrary to common observation; and it may be presumed, as suggested by Dr. Holland, that the increased labours of the peasantry in the early part of the spring, being speedily followed by the development of the symptoms, must have some influence on their production at this particular period. Perhaps, also, adds the same observer, the periodical returns of the pellagra, during its early stages, depend in part on the natural periodical changes of the body itself, independently of the external causes just alluded to.

It must be acknowledged that the chain of connection between the causes of pellagra and its specific symptoms has not hitherto been distinctly traced; but we know from universal experience that identity of disease has a common origin in a prevailing insufficiency of food, or in the use of such as is depraved or innutritious in its quality: we know, moreover, that the combined evils, already detailed, in the moral and physical condition of the people who become subjects of pellagra, have at all times been observed in connection with the prevalence of analogous disorders, which have been variously described under the comprehensive name of leprosy. It is further evident that the end of the several processes subservient to alimentation demands a sufficient and suitable supply of aliment; and in defect of either, the immediate wants of the system, as well as the imperfect actions of the various organs, become evident by the train of phenomena constituting the symptoms of disease. Added to and aggravating these in pellagra, we have the direct action of an irritant (the sun's heat), which, besides the local effect, and its direct consequences upon the nervous system, must, by impeding the important function of the cutaneous secernents, reflect their uncliminated material through the medium of the circulation over the whole body, and thereby help to generate its universal disorder. When we further consider the diversity of modifying influences, the mutability of their nature, and their relative operation, we cannot be surprised at the diversified appearances, nor at the endless discussions on the identity of diseases of this nature, arising no doubt from the unwarrantable habit of endeavouring always to limit to the arbitrary signification of a name circumstances confessedly Proteian in their nature, and which have a very distant analogy to the distinct and circumscribed

characters proper to objects of natural science, the classifications of which have been the models of nosological imitation.

The treatment of pellagra, like that of other endemic diseases which have their origin in the privation of the necessaries and comforts of life, has been infinitely diversified, and, according to general acknowledgment, unsuccessful. The patients on their admission into the hospital (we quote Dr. Holland) are immediately allowed a nutritious diet, and, unless contra-indicated by some local affection, wine and tonic medicines are given with the same view. A decoction of the lichen Islandicus is in common use in the hospital of Milan, as a part of this plan of dict. The warm bath is very generally employed at the same time; a favourite remedy among the peasantry, probably in consequence of its comparative cheapness, but esteemed also by most of the medical practitioners who are concerned in treating the disease. Diaphoretics, and especially antimonials, are in considerable use, under the idea of correcting the state of the skin, and getting rid of the morbid humours through this channel. Depletion by bloodletting is very rarely employed except where some local inflammation happens to occur, or in the mania which sometimes supervenes upon the disease. Attention is of course paid to the bowels in correcting the diarrhœa, and bringing them as far as possible to a natural state.

Besides these means, a long list of medicines, commonly termed antiscorbutics, are in popular use; but having mentioned the various preparations of cinchona, sarsaparilla, guaiacum, sassafras, cantharides, terebinthina, and mercurials, it would be superfluous to enumerate the thousand remedies for this hitherto untractable and fatal disease.

From the preceding detail it is evident that the labour of physicians in the treatment of pellagra must continue in its results to resemble that of Sisyphus, until a decided amelioration can be effected in the moral and physical condition of that unfortunate class of persons in whom it is found to occur; and all former experience of diseases analogous in their nature justifies us in asserting that when, and not till when, it ceases to be the opprobrium patriæ, will it cease also to appear to be the opprobrium medicorum.

[The following are the conclusions drawn by M. Brière de Boismont, from a careful study of the disease in the districts where it reigned epidemically:

First, pellagra is, at times, a primary irritation of the digestive organs, complicated with irritation of the nervous and cutaneous systems; at others, it is a disease of innervation, with secondary lesion of the digestive functions. In many cases, the nervous system alone is attacked. The affection of the skin, which is sometimes wanting, and not always in a ratio, as regards intensity, with the other symptoms, and which may even disappear without the disease being cured, is evidently consecutive in all cases without exception. *Secondly*, the symptoms, causes and lesions, leave not the slightest doubt as to the inflammatory nature of the disease, and its true seat. *Thirdly*, the exciting causes of pellagra belong to the class of irritants and debilitants. *Fourthly*, the pathological alterations found in the digestive, cerebro-spinal, and external tegumentary systems, are the products of inflammation. *Fifthly*, the three stages are not always as distinctly defined as has been pretended; the second, which is almost constantly mortal, if the circumstances are not changed, may remain stationary for many years. The third is incurable. *Sixthly*, removal from the locality, and change of life, exert a happy influence on the disease, which is not contagious, but is hereditary, and has a constant tendency to extend. *Seventhly*, the antiphlogistic treatment appears to be most successful; but to arrest the progress of the scourge, it is indispensable to have recourse to proper hygienic and administrative measures.]

WILLIAM KERR.

PEMPHIGUS, from *πέμφιξ*, *a bleb*, or *blister*. This disease belongs to the order *Bullæ* of cutaneous diseases. Under the present heading we shall include both pemphigus and pompholyx, as we consider the latter as merely a variety of the former.

Previously to the time of Willan, nosologists made a distinction between these diseases, describing pemphigus as an idiopathic cruptive fever (*febris pemphigodes*), running through a certain fixed course like measles or scarlatina, and pompholyx as differing from it, in not being accompanied by fever; and this view is still supported by some writers on skin diseases. An additional line of demarcation was supposed to be found in the local characters of the eruptions; pemphigus being supposed to present bullæ with inflamed edges, and pompholyx to consist of bullæ without inflammation or redness around them. These distinctions will not bear examination. The fever which sometimes precedes or accompanies the bullæ of pemphigus, makes no approach to the regularity of the fevers of measles or scarlatina, but is, on the contrary, very irregular in its nature and duration. It may be a short inflammatory fever, or of a low typhoid type, or it may assume the characters of an intermittent. The period of the fever at which the eruption of bullæ appears, is equally uncertain. The bullæ may appear almost simultaneously with the accession of febrile symptoms, or on the second day of fever, as in the case related by Seliger, and referred to by Dr. Willan; or on the second accession of an attack of intermittent fever, as in the case related by Dr. Winterbottom; or on the fourth day of low typhoid fever, as in the case related by Dr. Dickson in the first volume of the Transactions of the Royal Irish Academy. The bullæ may be still more irregular in their eruption, coming out in successive crops at uncertain periods of a continued fever, and, lastly, may appear either as sympathetic with or as a crisis of internal visceral disease. These irregularities of the type of the fever, and of the coming out of the eruption, are sufficient to convince us that pemphigus has no claim to the title of an idiopathic eruptive fever. The further supposed distinction between it and pompholyx, of the bullæ of pemphigus having a red inflamed edge, and those of pompholyx not possessing this character, will prove equally invalid; for this character is merely accidental.

The bullæ will possess or will be deficient in this character, according to the time at which they are examined. In almost every instance a distinct circular erythematous patch upon the skin precedes the formation of each bulla. If the bullæ be examined before having attained a sufficient size to occupy the entire of the erythematous patch, there will then be seen around the circumference a red inflamed edge formed by the outer margin of the erythematous patch not yet occupied by the bullæ; but if not examined until a later period, or if even examined at a very early period, when (as in pemphigus solitarius) the growth of the bulla is very rapid, then the entire of the precursive erythematous patch will be covered by the bulla, and there will be no surrounding blush or tumefaction; or, in other words, the disease will be the pompholyx of some authors. These are our reasons for considering pompholyx as merely a variety of pemphigus.

Pemphigus may be defined "an affection of the skin, consisting of the eruption of one or more bullæ containing serous fluid, and terminating either in thin scales, in superficial excoriations, or in ulceration."

The immediate pathology of pemphigus is an effusion of serous fluid from the surface of the rete mucosum, which first detaches portions of the cuticle, and then distends them into bullæ. In most instances there are erythematous patches upon the skin preceding the appearance of the bullæ. Between these the skin preserves its natural appearance, or seems very slightly swollen. If the finger be passed over the surface, each erythematous patch gives a sensation, arising from the local congestion, of being a little firmer and more elevated than the surrounding surface; but there is no marked increase of thickness or hardness of cutaneous or cellular tissue, such as is found in the commencement of pustular diseases. The bullæ first appear on the centres of the erythematous patches; and around each bulla there may or may not be a red margin according as the bulla occupies only the central portion, or has spread over the whole of the inflamed base from which it has arisen. The skin between the bullæ continues to preserve its natural appearance and colour. The bullæ always commence as such, and never as papulæ or pustulæ; in the commencement they are translucid, either colourless or of a pale fawn or slightly bluish cast; and as they continue to grow, they assume a hemispherical shape, and present different sizes from that of a split pea to a size sufficient to contain a teacupful of fluid. The fluid contained in the bullæ consists principally of albumen; it readily coagulates by heat into an almost solid mass, and sometimes, although rarely, the albumen of a bulla is in such quantity as to coagulate spontaneously and form a layer lining the distended cuticle. The fluid of the bullæ is usually bland and devoid of smell, but, in some varieties of the disease to be afterwards noted, gives out a most disagreeable fetor, and seems to acquire acrid properties. When the bullæ are fully formed they become opaque, and sometimes, from a trifling admixture of purulent matter, present a yellowish, or greenish yellow shade. Arrived at this stage, they may terminate in various ways. In mild cases the smaller sized bullæ, after having reached their greatest degree of development and tension, begin to wither; the cuticle wrinkles; and the albuminous portion of the effused fluid, together with the detached cuticle, dries into a thin brownish scab, which, falling off, exposes a red patch formed of the inflamed true skin, with its thin new cuticle. The larger sized bullæ burst either spontaneously or through accident; and the broken cuticle, lying flat upon the inflamed surface, now dries away into a scale, which separating, exposes, as before, the red base on which the bulla arose. For a short time after the larger bullæ are opened, the inflamed excoriated surface continues to secrete a fluid similar to that originally effused. In weakly constitutions, after the bullæ have burst, the inflamed surface of the true skin, instead of furnishing a new cuticle, takes on the action of secreting pus; and if the pus or scab formed of it be removed, then presents the appearance of an indolent ulcer. In more severe forms of the disease, the fluid of the bullæ is thin and ichorous, forms no crust, and when discharged by the bursting of the cuticle, exposes an unhealthy-looking flabby ulcer; the tissue around softens, and the ulcer continues to spread as a gangrenous ulcer, engaging in its destructive progress all the surrounding tissues without distinction.

No portion of the cutaneous surface is exempt from the invasion of pemphigus. It may confine itself to a part, or may spread itself over the entire surface; but the parts on which the eruption most frequently appears are the limbs, particularly the lower limbs, and the skin of the abdomen. The bullæ also make their appearance on the mucous membrane of the mouth and of the vagina. One variety of the disease (pemphigus gangrenosus) has a tendency to attack in preference the skin behind the ears and the folds of the thighs.

Pemphigus may make its appearance as an idiopathic disease, or as sympathetic of some internal visceral irritation; or its bullæ may occur during the course of other diseases, more especially those of the skin, principally erysipelas, herpes, prurigo, scabies, and varicella. It is asserted by some writers that the bullæ of pemphigus are occasionally found on the mucous membrane of the stomach and intestines. Rayer admits the occasional existence of bullæ on the mucous membrane of the mouth, but denies their existence in the stomach and intestines. Of their occasional existence in the mouth there cannot be a doubt. In the case related by Dr. Dickson, and already referred to, the patient, a delicate woman, twenty-three years old, felt on the third day of low fever a tingling pain and smarting in the tongue and inside of the mouth. On the next, the fourth day, a pellucid bulla appeared on the tongue one inch long, and half an inch broad, turgid, with faintly yellowish serous fluid, and a smaller one on the inside of the left cheek. The sensation felt was as if these bullæ were full of scalding water. On the fifth day, bullæ appeared over the body; and on the ninth day the bullæ of the mouth left behind them an excoriated and acutely sensible surface.

In the abdominal viscera the changes observed most frequently in fatal cases of pemphigus are redness, softening, and ulcerations, the ordinary

effects of gastro-enteritis. Biett states that the internal derangement which he has observed most constant in pemphigus is the fat liver.

Diagnosis.—Vesicles, or bullæ, are sometimes found in erysipelas which bear a close resemblance to pemphigus; but they are at once distinguished by the whole surface of the skin on which the vesications appear in erysipelas being tense, shining and red. The vesicles of herpes somewhat resemble the bullæ of pemphigus; but exclusively of being much smaller and irregular in form, they are always clustered upon a red inflamed surface; while the bullæ of pemphigus are scattered, the skin between them preserving its natural appearance. The extremely small size and immense numbers of the vesicles of miliary eruption furnish us with a well-marked line of distinction between it and pemphigus. Varicella, or chicken-pox, when fully developed, presents vesicles, which, however, are easily distinguished from the bullæ of pemphigus by being pretty equally diffused over the entire body, and by all being of nearly one size, and much smaller than the bullæ of pemphigus.

Rupia has some characters in common with pemphigus, and belongs to the same order; but in rupia the bullæ are generally fewer in number, smaller, less tense, and more flattened than in pemphigus, and the contained fluid quickly becomes sanious or purulent. The cutaneous tissue around the bullæ of rupia is more deeply inflamed; and the bullæ, after having reached their full growth, instead of forming thin crusts or excoriations as in pemphigus, are followed by thick prominent scales, which, when removed, expose deeply-eaten ulcerations.

These are the only diseases which can be confounded with pemphigus. The characters distinguishing pemphigus from all other affections of the skin are so marked, that it is quite unnecessary to point them out.

Prognosis.—It may be laid down as a general rule that the more acutely pemphigus sets in, the less dangerous it is; and as it shows a tendency to become chronic or occur in weakly constitutions, or is accompanied by a fever of a low typhoid type, the more unfavourable is its prognosis.

Causes.—Whatever acts directly as a stimulant to the skin, or indirectly injures its function through the medium of the constitution, or of the mucous tissue of the digestive organs, may be an exciting cause of this disease, viz. exposure to the direct and burning rays of the sun, or the application of any irritating substances. Among mowers in Ireland, a local form of pemphigus attacks the skin over the ancles, and is a very troublesome complaint. It is by the men themselves attributed to the seeds of the cow parsnip (*heracleum sphondilium*). The bites of some serpents, the prolonged impression of cold or damp upon the surface previously over-heated, excess in the use of spirituous liquors or heating spices, depression of mind, marsh residence, debility however induced, are also in the list of exciting or of predisposing causes. The disease has supervened on the suppression of the lochia, of the menstrual discharge, of hemorrhoids, and of diarrhœa.

The bullæ of pemphigus occasionally accompany epidemic diseases, such as scarlatina; and from this complication has arisen the description of pemphigus Helveticus as an epidemic given by Laughans. There is, however, no authentic description of simple pemphigus prevailing as an epidemic.

Pemphigus is a disease of all climates and seasons; but one variety, pemphigus gangrenosus, is generally confined to certain districts as an epidemic disease: we shall have occasion to speak more at large on this form of it. Cullen, in his "Synopsis," characterizes pemphigus as a contagious disease; but at the same time observes that he has only followed Sauvages, and that he has no knowledge of the disease from personal observation. Experiment is unfavourable to the supposition of the disease being contagious. Husson inoculated five children with fluid taken from the bullæ of pemphigus, and the disease was not in any instance transmitted. (Recherches Historiques et Médicales sur la Vaccine.) Martin confirmed these by similar experiments. (Journal de Médecine, Chirurgie, et Pharmacie, vol. ii. p. 225.)

The varieties of pemphigus may be considered with most practical advantage under the heads of *acute pemphigus*, *chronic pemphigus*, and *gangrenous pemphigus*.

1. *Acute Pemphigus.*—This variety is preceded by febrile symptoms of very uncertain characters. There is generally a premonitory shivering fit very well marked, and in some cases there are two or more shivering fits so distinct, that the attack at first sight appears to be intermittent fever. In other cases, after a fit of shivering, there are the symptoms of continued fever—thirst, loss of appetite, coated tongue, and dry hot skin; and after these have continued usually from one to four days, the surface about to become the seat of the eruption, generally the skin of the abdomen and lower extremities, in a few cases of the whole body, is affected by a sensation of tingling heat, and circular red patches of various sizes come out, irregularly scattered over the surface; their colour will not disappear under pressure, and within twenty-four hours of their appearance bullæ arise on these patches and rapidly increase, until each bulla occupies the entire or nearly the entire of the inflamed plane on which it has arisen. Some of the bullæ, although rarely, become confluent. The bullæ having arrived at their full size, usually within the period of two or three days from their first appearance, become turgid, burst, and discharge their contents, leaving the surface of the true skin now exposed, red, excoriated, and painful. The pain is like the sensation produced by a burn or scald, and is not felt until the true skin is exposed by the bursting of the bullæ. The exposed cutis is, however, soon covered by a thin crust formed by the old cuticle, the remnant of the contained fluid, and a secretion of similar fluid, which continues for a short time from the inflamed surface. The thin scab thus formed, after a few days drops off, and exhibits the true skin covered with a new cuticle, and of a dark red colour. This colour remains for an uncertain time. The febrile symptoms which ushered in the disease usually abate on the appearance of the eruption, and continue in a mild degree until the healing of the broken bullæ. In a very great majority of

cases the termination of the attack is a marked crisis, either by diarrhœa or a copious deposition from the urine.

The duration of acute pemphigus is very uncertain. It never runs its course in less than a week, and is seldom prolonged beyond a month. When gastro-intestinal irritation is superadded, the symptoms are aggravated, and in such cases the mucous membrane of the mouth may present bullæ resembling those upon the surface, but, from being constantly bathed in moisture, not forming scales. There is a form of acute pemphigus, in which, after heat, itching, and redness of a part, a single bulla arises, (pompholyx solitarius of Bateman,) and after becoming enlarged to a size sufficient to hold a tea-cupful of fluid, bursts, and is, perhaps, succeeded by another following the same course. In this variety, if a bulla burst before it has attained its full size, it may heal in the centre, and the circumference of the bulla continuing to increase, will produce the appearance of the whole cuticle of the part peeling off.

Treatment. — The treatment of acute pemphigus, when it exists as an idiopathic affection, is very simple; the febrile symptoms not generally running so high as to demand very active treatment. Mild purgative and diuretic medicine and cool drinks are generally all that are required. If the disease be complicated by gastro-intestinal irritation or inflammation, or be sympathetic with the disease of any important internal organ, the cutaneous affection becomes of secondary importance; the internal disease demands all our care. Warm baths, or any heating application to the skin, are improper in acute pemphigus. It is recommended in some works to open the bullæ as soon as they are formed. This is not judicious practice. The distress of the patient is comparatively little before the bullæ have burst; but after this there is, as we have already noticed, a most painful sensation of burning, produced by the exposure of the raw surface of the true skin. The febrile excitement is thus increased, and we shall both hurry and prolong the pain and fever if we unnecessarily puncture the bullæ. We can apply to the excoriated surface no dressing so mild as its own albuminous secretion, and can protect the excoriated skin from the irritation of exposure by no covering so effectually as by its own cuticle. When the bullæ have burst, either spontaneously or by accident, and the excoriated surface is scalding and painful, the denuded part should be covered with the mildest dressing, with slips of gold-beater's leaf, or the delicate membrane which lines the interior of an egg-shell. When the bullæ are withering, and cicatrization is taking place, and after the fever has subsided, it becomes necessary to support the strength of the system, and aid it in its curative efforts by the exhibition of tonics, of which the best is cinchona or sulphate of quinine. Sometimes the fever which ushers in acute pemphigus presents almost from its very onset a low typhoid type; and while intestinal irritation is allayed by the mildest purgatives, the patient's strength requires to be supported by light broths, and, according to the symptoms, by wine and bark.

2. *Chronic Pemphigus.* — This variety of the disease is generally met with in old persons or in debilitated constitutions, is sometimes idiopathic, but more often sympathetic, with internal visceral disease; in the latter, of course, the more serious. It is the *pompholyx diutinus* of Bateman, *dartre phlycténoide confluente* of Alibert. This is a very obstinate and distressing form of skin disease, and there is scarcely any limit to its duration. After premonitory symptoms of lassitude, headach, &c., bullæ appear on different parts of the body. These heal, and are succeeded by others, which, as the patient's strength becomes weaker, show a disposition to ulcerate. There is intolerable pain and burning, from the exposure of the denuded cutis, and irritative fever sets in. A crisis may now take place, either by diarrhœa or by a copious deposition from the urine; the bullæ dry up and heal, the symptoms of irritative fever disappear, and the patient believes there is a perfect cure; but after a short interval the disease again shows itself. There is less disposition in the bullæ of each successive eruption to heal; the constitutional irritation produced by the numerous excoriated surfaces prevents rest, destroys appetite, and finally wears out the patient by exhaustion; or the constant irritation aggravates to such a degree some internal lesion, otherwise of little consequence, that a new train of symptoms sets in, the pemphigus disappears before some more formidable affection, and the patient dies of internal visceral disease. The bullæ of chronic are always larger than those of acute pemphigus, and, as already observed, are more generally sympathetic with some internal disease of function or of structure than an idiopathic affection of the skin. Persons advanced in life are more subject to chronic pemphigus, and whatever debilitates the constitution, as mental depression, or bad or insufficient food, or injures the functions of the skin, as a residence in cold damp situations, may tend to bring forth the disease; and in cases where the previous debility has been very great, the bullæ not only ulcerate, but the surface on which they have arisen sloughs around the bullæ to a considerable extent.

Treatment.—As this disease is so frequently a symptomatic affection, the treatment is in general complex, and must in such circumstances be directed as much to internal visceral disease as to the external skin affection. For the treatment of the rheumatic, gouty, or visceral derangements which may be combined with chronic pemphigus, we of course refer our reader to the various heads under which those derangements are considered. Internal irritation (if any) being allayed by appropriate means, the patient who is the subject of chronic pemphigus is then to be put upon a full and nourishing but not stimulating diet, and tonics combined with diuretics, as sulphate of quinine with compound infusion of juniper, or bitters with alkalies, are to be administered. Locality has often much influence over this disease, and hence, if the ordinary measures above recommended are not successful, change of air should be enjoined, and the change should always be to a dry air and a high situation. The bullæ should not be opened by art, for the same reasons as given for not opening the bullæ of acute pemphigus. If the bullæ burst and leave indolent ulcerations, these are to be stimulated with powdered bark or burnt alum,

or touched, if necessary with solid nitrate of silver. Warm baths generally aggravate this disease when present, but are very useful as preventives by preserving the skin in the exercise of its healthy functions.

Before we proceed to the third variety, gangrenous pemphigus, it is necessary to mention a form of pemphigus which does not perhaps strictly come under any of the heads we have named. For practical utility we have described two forms of pemphigus, as acute and chronic; but here, as in most diseases, this line of distinction is more arbitrary than real, the two forms running into one another by imperceptible gradations: perhaps the term subacute, borrowed from the French, would be the best name for the variety of pemphigus to which we now allude, and which forms the connecting link between the acute and chronic forms. This variety of pemphigus corresponds with acute pemphigus in being accompanied with fever, but agrees with chronic pemphigus in presenting, not simultaneous, but successive eruptions of bullæ. It is called by French writers "pemphigus aigu successif." The accessions of febrile symptoms are irregular, and with each accession a new crop of bullæ appears on the skin, the whole attack usually running its course within a few weeks. The treatment is merely a modification of that recommended for acute pemphigus, with this addition, that as the fever which precedes the eruption takes on an intermittent form, the early exhibition of bark is called for.

3. *Gangrenous (or infantile) Pemphigus.*—(Pemphigus infantilis of Willan, rupia escharotica of Bateman and Biett.) Bateman and Biett place this disease under the head *rupia*, but improperly, for the fluid of the bullæ in this disease is a thin sanious ichor, neither forming thick crusts, nor turning purulent, which are the distinguishing characters of rupia. This form of pemphigus is exclusively confined to children, and very rarely attacks them after the age of five years. In many parts of Ireland this singular disease prevails to a great extent, principally among the children of the poor, and appears to be in some situations an endemic disease, but from time to time breaking out as an epidemic, attended with great mortality. This latter circumstance has probably originated the belief in the contagious nature of the disease, very generally entertained by the people of the districts where the disease is prevalent. There are, however, no satisfactory proofs in support of this opinion. Dr. Macbride, in his "Methodical Introduction to the Theory and Practice of Medicine," notices an outbreak of this disease. "In the county of Wicklow, about twenty miles from Dublin, a disease of this kind (as the author has been informed) appeared in the year 1766, but attacked only children, many of whom were carried off, until the cortex was thought of as a remedy, and found equally efficacious as in the malignant sore throat." It is singular that in the same county the disease is still prevalent. It is known in different parts of Ireland under the various popular names of "white blisters," "burnt holes," "eating hive," &c. No systematic work on diseases of the skin contains either full or accurate information on this singular form of pemphigus. To Dr. Whitley Stokes we are indebted for our knowledge of its symptoms and treatment, and we cannot give that information in better words than his own.

"The approach of this disorder is sometimes, though rarely, denoted by a livid suffusion like that of erysipelas slightly elevated. This was both observed by Dr. M'Donnel of Belfast, and by Dr. Spear, in the county of Monaghan, at a time when the disease prevails there epidemically. It more frequently happens, however, that the complaint comes on in perfect health. One or more vesicles appear, mostly larger than the best distinct small-pox; these increase for two or three days, burst and discharge a thin fluid having a disagreeable smell, limpid in most cases, sometimes whitish, and sometimes yellowish, the latter less dangerous; usually the weaker the child's constitution is, the thinner is the matter. Before or after breaking, the vesicles run together, the sores become painful, with loss of substance and a thin fetid ichorous discharge; the edges of the ulcer are undermined, and it spreads quickly. The more usual seats of the disease are behind the ears, sometimes on the hands or feet, on the private parts, (seldom on the arm-pit), the breasts, folds of the thighs, lower belly, on the inside of the mouth or lips. The disease, however, it is said, seldom passes from the inside to the outside of the mouth. In the progress of the disorder, the ulcers enlarge rapidly, with remarkable fetor, very great discharge, and livid edges. If the sores are behind the ears, they destroy the connection of the posterior cartilage with the cranium; they spread to the meatus auditorius; to the eyes, the sight of which seemed in a few cases to have been destroyed one or two days before death; and they sometimes extend to the vertex. The constitutional disturbance that accompanies this disease seems principally the effect of irritation. When the vesicles burst, the child begins to grow peevish and fretful, pale, loses its appetite, and the flesh becomes remarkably flabby. The periods of this disorder are not very regular; but it often happens about the eighth day that the pulse sinks, the lividity spreads over the whole sore, the fetor and discharge increase greatly. The smell is so strong as often to be perceivable at a distance from the bed. The discharge in one case where the ulcers affected the arm-pits and breasts, was such that the linen was completely loaded several times a day. Death takes place about the tenth or twelfth day, often preceded by convulsions, sometimes by extreme debility. Patients are apt to relapse soon after the sores are skinned over. The causes of this malady are rather obscure. It seems exclusively confined to children. Dr. M'Donnel saw twenty cases before the year 1795; all the patients were under four years old. Dr. Spear observed that it was confined to children from the age of three months to that of five years; but it has been observed near Dublin in children of nine years old. It attacks the finest children in preference; the children of the poor more frequently than those of the affluent; and those who live in damp situations seem more peculiarly subject to it than others. The disease is more prevalent in summer than in winter. It appears to be infectious, though obscurely so in general; but in the year 1800, Dr. Spear observed it to spread epi

demically. It has been said that the disease oftener affects the younger from the older than the reverse. It would be interesting to determine whether it attacks the same person twice; it certainly is apt to return after apparent recovery. Children, as is well known, are subject to excoriations behind the ears which sometimes produce formidable sores; these may, possibly, in a few cases, resemble the discase we speak of, in its advanced stages; but in a great majority of these cases these excoriations are far less rapid and dangerous than the complaint in question. On the other hand, the swine-pock (varicella) resembles this discase in its first stage; but the fever rarely precedes the eruption in white blisters, and pustules of varicella dry readily.

"This is a disorder of great danger, but of various progress in different individuals. It often happens that a fatal change takes place about the eleventh day. The unfavourable signs are, the rapidity with which the sores spread; the blackness, first at the edges, after some time spreading over the whole; the quantity and fetor of the discharge; its colour, the paler being the most dangerous.

"It has been alleged by empirical practitioners in this discase, that after the blackness had covered the whole sore, death was certain; but I have observed the blackness to go off, although it had spread over the whole surface of the sores. When this appearance abates, livid streaks generally remain for a day or two. When a favourable change is effected in bad cases, the diminution of the fetor and discharge were the first signs of the abatement of the malady; appetite was afterwards restored."*

Dr. M'Adam, in a paper on this disease in the same journal, (vol. i. p. 307,) states that the discharge from the vesicles is acrid, and that he has seen erosions produced on the breast by fluid which fell accidentally from the vesicles. This disease was very fatal and very unmanageable in all its stages. Dr. Willan says, speaking of pemphigus infantilis, that treatment was attended with little success. All ordinary modes of treating the disease having failed, Dr. Stokes was led to search after a traditionary empirical cure, of which he had heard a favourable report. He carefully watched over some cases treated by a person who professed to possess the secret of curing the disease, and having satisfied himself that the treatment was successful, he made himself acquainted with its details. The principal application was a compound green ointment composed of a great number of herbs, some active and some inert. From one plant "scrofularia nodosa" (*great fig-wort*) occurring in several receipts which Dr. Stokes procured, he was led to fix upon a simpler ointment made from this plant alone; the following are his directions for treatment. "When the parts adjoining the sores are swelled, and strongly suffused with a dusky redness, or if the sores have been previously dressed by any dry powder, I apply a poultice of porter and oatmeal. The carrot poultice in fermentation, if it can be procured without any delay, would perhaps be useful. After about eight hours the poultice should be removed, and the parts affected very gently wiped with a roll of lint or soft rag; then the scrophularia ointment should be applied. It should be as highly saturated with green vegetable matter as possible. For this purpose the plant should be taken fresh, the smaller leaves selected, and stewed a considerable time with as small a quantity of unsalted butter as will be sufficient to prevent the leaves from being scorched. If well prepared, it is of a full grass-green colour; but after keeping it becomes the colour of box leaves, especially at the surface; yet I apprehend it preserves its efficacy, in a great degree, for many months. When applied, it should be melted and suffered to cool to the consistence of honey; it should be applied by a soft feather, with the utmost gentleness, to the whole surface of the sore. Through the whole of the treatment, the greatest gentleness should be used. If the ear is strongly drawn open, the parts affected are made to bleed, which produces many inconveniences, and retards the progress of the cure. After smearing the ulcer with the ointment, it should be dressed with the same ointment, with the addition of one-eighth part of wax. The last ointment should be spread on lint folded to the dry side, and cut so as to fit behind the ear; the whole should be secured by a broad bandage, drawn under the chin, and fastened over the top of the head. This dressing, in very severe cases, should be repeated every fourth or sixth hour; but as the fetor abates, larger intervals may be allowed. I do not pretend that this treatment will always succeed; but perhaps, of four such cases as may occur to any practitioner, not excluding the most hopeless, it will succeed in three on an average: and if we could accurately ascertain the mortality which takes place when other methods are used, we should consider this proportion of success as very satisfactory." This ointment is now introduced into the Dublin Pharmacopœia, and is found a most useful application, not alone in the disease here noticed, but in many other affections of the skin and scalp. Dr. M'Adam, in the paper already alluded to, speaks favourably of the internal exhibition of cinchona in this disease, and of the external application of strong ung. hydrargyri nitratis.

D. J. Corrigan.

PERCUSSION. See Auscultation, and Chest, Exploration of the.

PERFORATION OF THE HOLLOW VISCERA.—This term is generally employed to designate a solution of continuity, in consequence of disease of the walls of a hollow organ. The term *spontaneous perforation* has likewise been applied to those perforations which occur without having been preceded by any perceptible modification of function, local or general.

Perforation is far from being a rare occurrence in several organs of the body, and has been observed to take place under various circumstances in most of them. The relative order of its frequency may be stated as follows: the organs of respiration; digestive organs; organs of generation in the female; vascular system; urinary organs; hollow bones; the eye and the ear.

Perforation of the parietes of the three great cavities is occasionally observed, and perhaps more frequently in those of the abdomen and head than in those of the chest.

When perforation takes place in any of these parts, a preternatural communication is established between two or more natural cavities; between these and an accidental cavity formed in consequence of ulceration, mortification, or the accumulation of pus, blood, or other fluids in the solid viscera; and between one or both of these and the external surface of the body. Hence it follows that perforation may give rise to the effusions of a natural or accidental fluid into a serous or mucous cavity, or on the external surface of the body, and which, consequently, may be either retained or rejected.

Perforation may, however, occur without a communication being established between the perforated organ and a natural or accidental cavity. This is accomplished in two ways; 1st, by the union of a neighbouring organ with that which is perforated previous to the occurrence of this lesion; 2dly, by the formation of a false membrane between which and the surface of the perforated organ an organic union had previously been established.

Examples of these two modes in which a preternatural communication from perforation is prevented from taking place between two or more hollow organs, or between these and accidental cavities, are often met with in the abdominal and thoracic viscera. One, two, or more portions of the small intestine are found more or less firmly united over ulcerations of greater or less extent which occupy in depth the whole of the coats of these portions of intestine. A portion of the epiploon has been found adhering to the surface of the intestine or gall-bladder, and covering perforations of these organs; and the liver, spleen, pancreas, mesentery, transverse arch of the colon, and diaphragm, furnish striking examples of the means which nature employs to supply the loss of substance occasioned by several diseases, of all the coats of the stomach, and to prevent a communication from taking place between the cavity of this organ and that of the abdomen and thorax. Similar examples are met with in the lungs when these organs are the seat of tubercular excavations. The walls of these excavations, particularly when they occupy the upper lobes of the lungs, are often found to be formed in great part by those of the chest, the pleura pulmonalis and costalis over the excavation being intimately united by immediate contact, or by means of dense cellular or *cellulo-fibrous* tissue.

The second mode of prevention of a preternatural communication from perforation, viz. the formation of a cellular or serous membrane, is much less common than the former. The presence of this accidental serous or cellular membrane may be confined to that portion only of the walls of the organ in which the perforation exists, or it may extend over the greater part or even the whole of the serous surface of the affected organ. It is almost always of a limited extent on the peritoneum when it forms a barrier to the escape of the contents of the intestines into the cavity of the abdomen, and more or less extensive on the pleura when it accomplishes a similar purpose, namely, when it prevents air, pus, or other fluids contained in the lungs, from passing into the cavity of the chest.

Perforation has been found to occur in consequence of ulceration, mortification, inflammatory softening, and chemical dissolution. Among these organic lesions, those which give rise most frequently to perforation are ulceration and mortification, because of these diseases occurring in almost every organ of the body. Inflammatory softening and chemical dissolution being, on the contrary, met with only in certain organs, are much less frequently the causes of perforation.

We shall now take a general view of perforation as it occurs in the different organs of the body in consequence of one or more of the lesions we have named, and shall confine ourselves to the description of its anatomical characters, and such other circumstances as may appear necessary to illustrate this part of its pathology, as the symptoms and treatment will be given in the history of those diseases by which perforation is preceded or followed, and to which we shall occasionally refer.

1. Perforation of the Digestive Organs —This lesion most frequently occurs in that portion of the digestive tube situated beneath the diaphragm, and more frequently in the intestines than in the stomach. In both it may occur either during life or after death. In the former case it is the consequence of ulceration or mortification; in the latter it depends on the presence of an acid, formed most frequently in the stomach during the process of digestion. It occurs besides in the stomach in consequence of the introduction of irritant and acid poisons.

We are not disposed to believe, and we think that facts are wanting to prove, that perforation of the stomach or intestines takes place in consequence of inflammatory softening of the walls of these organs; but as the facts on which we found this opinion will be given in detail in the article Softening, we shall not enter at present upon the investigation of the numerous and important questions which this subject involves.

1. Perforation of the superior portion of the digestive tube is occasionally observed to take place in consequence of several of the diseases to which it is subject, as well as from some others which occur in some of the neighbouring organs. In the œsophagus it is occasioned perhaps most frequently by cancer, formed either in the walls of this tube or in the cellular tissue external to it. In this case the walls of this muscular tube may be destroyed within a limited extent without any communication being formed between it and any neighbouring cavity; or, if the disease extends to the trachea or pleura forming the mediastinum, a communication may be formed between the cavities of both, and that of the œsophagus, through which a portion of the food and drink of the patient may pass, and give rise to the most distressing symptoms. It is indeed owing to this circumstance alone that we are enabled to detect the existence of such a communication, at least between the trachea and œsophagus.

The upper part of the œsophagus behind the larynx is sometimes the seat of ulcers, which, ea

tending to the cellular tissue situated between it and the latter, form collections of pus which impede mechanically, to a certain degree, respiration and deglutition. The inferior portion of the œsophagus has several times been found perforated, particularly in children, in consequence, we believe, of the chemical action of the gastric acid after death.

Aneurisms of the aorta occasionally produce perforation of the œsophagus, into which the blood is effused in greater or less quantity, so that the patient may live only a few hours, or several days, after the occurrence of the accident. In some cases there is no difficulty of swallowing from compression of the œsophagus, so that the progress of the aneurism in that direction is not suspected till the perforation takes place. In others, this termination of the disease may be predicted from the obstacle opposed to the passage of the food or drink.

Perforation of the velum and palate is generally observed to take place in consequence of ulceration or necrosis, and in those persons who have taken large quantities of mercury for the cure of venereal diseases.

Perforation of the stomach occurs in consequence of ulceration and mortification of a limited portion of its walls. The ulcer which is found to have produced the perforation generally bears the characters of having been produced by chronic inflammation, that is to say, its edges are hard and thickened, although sometimes neither of these states, particularly the latter, is present. The extent of the perforation compared with that of the ulcer is always small, and its border, which is formed by the peritoneum, is generally smooth. Perforation arising from this cause is met with in general at the small curvature or pyloric portion of the stomach, rarely at the great curvature, and perhaps never at the fundus.

Perforation of the stomach from cancer may be mentioned at present, as this disease gives rise to perforation not only from the softening of the tissue of which it is composed, but also from the ulcerative process which accompanies its latter stage. Perforation of the stomach from cancer occurs, however, most frequently on account of the softening or sloughing of the cancerous tissue when it occupies all the coats of the stomach, and on this account the solution of continuity produced by these changes is larger than that occasioned by any other cause during life, except when it follows the operation of corrosive poisons.

Perforation from cancer may occur in any portion of the stomach, but is most frequently met with at the pyloric portion and at the small curvature.

It is rare that perforation from this cause is followed by a communication between the cavity of the stomach and that of the abdomen, on account, as we have before stated, of some of the neighbouring organs becoming united to the stomach before the perforation is completed. This very circumstance however, which prevents the establishment of a preternatural communication between the stomach and the cavity of the abdomen, gives rise, at some future period, to those complicated cases of perforation in which a direct communication is formed between two or more of the abdominal organs, or between these and the contained viscera of a neighbouring cavity, or the external surface of the body. Examples of these three modes of communication are met with as the consequence of perforation of the stomach. Thus, it is not rare to find the walls of the transverse arch of the colon perforated where they had before occluded a perforation of the stomach, and a communication established between the respective cavities of these organs.

In the same manner is occlusion of a perforation of the stomach by the diaphragm followed by perforation of the latter, from which the ulcerative or sloughing process by which this lesion had been produced, extends to the inferior lobe of the lung, which had become united to the diaphragm. In this manner a portion of the lung is destroyed, several of the bronchi are laid open, and a communication formed between these tubes and the cavity of the stomach, and consequently between the latter and the external surface of the body. Lastly, it sometimes happens that the cavity of the stomach communicates with the external surface of the body, from the successive perforation of the walls of this organ and of those of the abdomen.

In all the examples of perforation of the stomach to which we have alluded, this lesion is represented as having taken place from within outwards. It may, however, occur in the opposite direction, or, as is said, from without inwards. Examples of this kind of perforation are rarely met with, except in cases of cancerous tumours situated in the left lobe of the liver, the mesentery, or mesenteric and lymphatic glands, and in scrofulous enlargement of the latter glands.

Mortification, so far as we are aware, has not been known to give rise to perforation of the stomach, unless when it has been produced by the presence of an accidental tissue, such as that of cancer, as in the cases to which we have alluded, or when it follows the violent operation of powerfully irritant or corrosive poisons, directly applied to the walls of this organ. In this latter case the vitality, and, to a certain extent, the organization of that portion of the stomach to which the poison has been applied, are destroyed. The portion thus circumstanced sloughs, and the cavity of the stomach, if adhesion has not taken place between this organ and a neighbouring one, is laid open, and its contents pass into that of the abdomen. The solution of continuity thus produced, may vary from the fourth of an inch to two or three inches in diameter, and has mostly a round form. Its edges are seldom irregular, and should they happen to be so, they are not thicker than the walls of the stomach, unless blood or serosity has been effused into the cellular tunic; the density of the tissues of which they are formed is seldom or only partially increased, and never so diminished that they assume a gelatinous consistence. The colour which they present is either that produced by an accumulation of blood in the capillarics, or by the effusion of this fluid into the cellular tissues which enters into their composition, or by the chemical action of the poison, either on the blood or on the tissues which form the boundaries of the perforation. In the former case the edges are more or less red, or vascular,

or both; in the latter they possess either a yellowish or orange tinge, or various shades of brown, amounting to black, as if they were painted with bistre, or dusted over with charcoal-powder or soot. Irritating poisons may produce the former appearances, but not the latter, which we believe are the effects of those poisons only which possess acid properties, as the nitric, muriatic, sulphuric, and oxalic.

The *post-mortem* appearances of perforation of the stomach from the introduction of acid poisons, in particular, into this organ, still require to be investigated with greater care than hitherto has been done, and particularly by means of a series of experiments on living animals, before we can affix to them that diagnostic importance of which they seem susceptible, or refer to them with confidence as medico-legal evidence in cases of poisoning. Perhaps even in the present state of our knowledge on this subject, may the toxicologist derive more assistance from the study of the *post-mortem* appearances of perforation of the stomach from acid poisons than is generally believed. But in order to do so, he must be intimately acquainted with those of all the other forms of perforation, particularly that produced by the gastric acid after death. We shall give a general sketch of the physical and chemical effects of this acid on the stomach, and endeavour to point out the means by which they may be distinguished from those produced during life by the acid or irritant poisons which have given rise to perforation.

Perforation of the stomach, in consequence of the chemical action of the *gastric acid*, takes place almost always in the most depending part of this organ, viz. the fundus. In those cases in which it has been met with in other parts of the stomach, accidental circumstances have concurred which afforded a satisfactory explanation of this difference as to its seat. The size of the perforation is generally large, often occupies the whole of the fundus, and sometimes a part of the body of the stomach. Its form is almost always irregular; its edges are thin, ragged, more frequently fringed or filamentous. The tissues of which it is composed are soft, pulpy, gelatinous, and more or less transparent; either perfectly pale, of a milky hue, or streaked with lines or stripes of a pale yellow, orange, brown, or black colour. These colours are always most marked in, or limited to, the mucous and submucous tissues, the muscular and serous coats which form the fringed edges of the perforation being quite pale. It is of the greatest importance to observe that these colours are always accompanied with softening of the mucous and submucous coats to a greater or less extent beyond the perforation; or, if these coats have been destroyed, the muscular is found similarly altered. If the blood-vessels, whether the capillaries or larger branches, were filled with blood at death, this fluid, wherever the coats of the stomach are softened, presents either the brown or black colour of chocolate or soot, and assumes of course the form and distribution of the vessels in which it is contained. Such is always the chemical effect of the gastric acid on the blood after death, and therefore we arrive at the important conclusion that redness, whether arising from the effusion of blood or vascularity, is incompatible with perforation from this natural chemical agent.

From these, the most remarkable of the *post-mortem* appearances which accompany perforation of the stomach from the gastric acid and acid poisons, it appears to us that such evidence may be obtained as will enable us to distinguish perforation produced by the former from that produced by the latter.

The pulpy, thin, transparent, pale, fringed edges of the perforation from the gastric acid; its situation in the fundus of the stomach; the presence of softening of the coats of this organ beyond the perforation, accompanied with discoloration of the blood only where this softening exists, and the entire absence of redness under any form in the same situation, are characters which we do not believe belong to any other form of perforation. Were it necessary to seek for still stronger evidence in favour of this opinion, we would refer to the histories of the cases of the individuals in whom these appearances have been found after death, to the results of our own experience on this subject in animals, and in particular to that strong collateral evidence by which it is supported, viz. the entire absence of all the anatomical characters of peritonitis, such as redness, increased vascularity, coagulable lymph, or adhesions in the neighbourhood of the perforation, and in general of effusion of the contents of the stomach,—consequences which may be said to follow invariably and to a greater or less extent, perforation of the stomach from the acid poisons, or indeed any other pathological agent.

If we are correct in our estimate of the distinctive characters of this kind of perforation, it follows that this lesion cannot be confounded with any other, however similar to it, but produced by a different agent. The analogy which exists between the former kind of perforation and that produced by acid poisons depends, as we have already said, on the acid property of these poisons, and because, therefore, of the same kind of discoloration being present in both cases. The difficulty thus created is, however, not such as it has been represented; nay, we believe that the embarrassment of the toxicologist has arisen from his not being acquainted with those *post-mortem* appearances which we have endeavoured to show are so peculiarly characteristic of the chemical action of the gastric acid. We may observe besides, that the local characters of perforation from acid poisons are in several respects very different from those of perforation from the gastric acid, as will be seen by comparing the description which we have given of them with those which accompany perforation from the gastric acid, particularly as regards the situation of the former, the character of its edges, and the redness of the tissues surrounding it, to which we may add effusion of the contents of the stomach, and peritonitis.

Perforation from cancer or chronic ulceration never can be confounded with that from the gastric acid.

Perforation in consequence of an ulcer of the stomach from common inflammation, neither acute nor chronic, cannot, perhaps, be distinguished from perforation produced by irritant and even acid poisons. But as facts appear to be wanting

on this part of the subject, we must leave it in its present state of uncertainty without any further comment.

2. *Perforation of the intestines* takes place most frequently in consequence of ulceration; and in the great majority of cases in the inferior portion of the ileum, in the situation of the *glandulæ agminatæ*, or glands of *Peyer*. It may occur also in the points of the small and large intestines occupied by the *glandulæ solitariæ*, as well as in those of both intestines in which no follicles exist. The ulceration which preceded the perforation may have been either acute or chronic, but is far more frequently of the latter kind, and may have given no signs whatever during life of its existence. The ulcerated portion of the intestine is found either pale or presenting various degrees of redness and vascularity, and is accompanied with similar states of the surrounding mucous membranes. The changes in the thickness and consistence of this portion of the intestines present considerable variety, and vary with the degree and duration of the inflammation by which they have been occasioned. The perforation is sometimes not larger than to admit a common-sized probe; at other times so large as to admit the point of the fore-finger, or even of the thumb. Its edges are generally smooth, and more frequently circular than of an irregular shape, and are formed by the peritoneal coat, except in some rare cases, in which the ulceration has destroyed to the same extent the other coats of the intestine. Perforation of the small intestines may occur in one, two, or three of the glands of Peyer in the same individual, and in either case it almost always gives rise to a communication between the cavity of the intestine and that of the abdomen, followed by an effusion of the contents of the intestine, and peritonitis.

Perforation from ulceration may take place in the rectum, caput cœcum coli, duodenum, and indeed throughout the whole of the large and small intestines, where the mesentery separates to be reflected over them, without giving rise to much effusion or a communication with the cavity of the peritoneum. But this variety of perforation is chiefly met with in the rectum and caput cœcum, and is no doubt sometimes the cause of the abscesses which not unfrequently form in the cellular tissue in the situation of these portions of the intestinal tube.

In the intestines, as in all organs covered by a serous membrane, perforation from ulceration is always preceded by *sloughing* of this membrane. When the ulcerative process has destroyed the sub-serous cellular tissue, and consequently the vessels which supplied it with the materials of its nutrition, it soon dies, and is separated in the form of a pale or grey-coloured slough, or tinged with the colouring matter of the bile or fæces, and without the odour of gangrene.

Perforation from mortification of all the coats of the intestines, is, perhaps, never met with, unless in some cases of intus-susception and strangulated hernia. In the former case, the fæcal matter passes into the cavity of the peritoneum; in the latter, a similar consequence may follow, but much more frequently adhesion takes place between the intestine, before it perforates, and the walls of the abdomen, when the perforation of both takes place, and a communication is established between the cavity of the intestine and the external surface of the body, or what is called an *artificial anus* is formed.

We are not aware that there is a single example of recovery from peritonitis produced by perforation of the intestines. The patient may survive the accident only a few hours, and seldom survives more than two or three days, the length of time depending chiefly on the previous state of the patient, and the quantity of the fæcal matter effused, although some cases have occurred in which the quantity of this matter was so small that it could hardly be detected either by its presence or odour, while the symptoms were violent, and the disease proved rapidly fatal. See Fever, and Peritonitis *from perforation of the serous membrane.*

Perforation of the intestine from poisons has not, so far as we know, been observed. There are, however, several examples of its having been produced by the gastric acid after death, but which have been regarded by some pathologists as the consequence of disease; an opinion, the accuracy of which will be particularly examined in the article Softening.

Perforation of the intestines from without inwards is occasioned by the same diseases as those mentioned as giving rise to this variety of perforation of the stomach. Tubercles and abscesses are, however, the most frequent causes of it in the intestines. We have seen the former perforate the intestine in a number of points, without any traces of inflammation of the mucous membrane around the perforation, and without a communication being formed between the cavity of the intestine and that of the peritoneum. The abscesses which perforate the intestines are retro-peritoneal, and most frequently those situated in the loose cellular tissue situated in the ilio-cæcal region. The coats of the intestines, generally the cœcum or commencement of the colon, are gradually destroyed by ulceration, and a quantity of pus in proportion to the size of the abscess is evacuated by the anus.

The preternatural communications which are found to take place between the intestines and neighbouring organs, in consequence of perforation of the former, we have already alluded to generally, and they are by no means so frequent as when they are occasioned by perforation of the latter. Sometimes portions of the small intestines are found united together, and communicating with each other by means of several perforations, through which the liquid fæces pass in greater or less quantity, and examples have been met with in which the passage thus formed was lined with an accidental mucous tissue. In the cases of preternatural communications of this kind which we have seen, the perforated intestines were included in a common accidental serous envelope, the evidence of peritonitis having existed at some remote period; and the coats of the intestine more or less destroyed by tubercular ulceration, commencing in the glands of Peyer. We do not believe that the peritonitis, in such cases, was the consequence of the effusion of fæcal matter from perforation of the intestine. We believe, on the

contrary, that it is produced before the perforation of the serous membrane is accomplished, so that the coagulable lymph which is thrown out becomes organized and united with a neighbouring portion of intestine. Afterwards the ulceration proceeds, and the preternatural communications we have described are effected.

Another variety of preternatural communication of the small intestines, and which takes place in a manner similar to the former, is that in which there exists cellular adhesions between the perforated portion of intestine and the walls of the abdomen. The effused fæcal matter is prevented by the presence of this tissue from passing into the cavity of the peritoneum. In this tissue it collects in greater or less quantity, and as the abdominal parietes with which it is in contact are more susceptible to its stimulating effects than the former, they become inflamed, ulcerate, and are perforated, and a communication is established between the intestine and the surface of the body, through which the fæcal matter escapes. Andral mentions a case of this kind. Besides the fæcal matter there escaped an ascaris lombricoides, and several of these worms were found, after the death of the patient, contained in the cavity formed in the accidental cellular tissue which united the perforated intestine with the perforated walls of the abdomen.

Although it is said that worms perforate the intestines, we have never seen a case of perforation which could in any way dispose us to attribute it to such a cause. Were such a case to happen, it could only be in consequence of inflammation and ulceration excited by these animals; and yet we have found them very numerous,—in one instance amounting to thousands,—without the slightest trace of inflammation of the mucous membrane.

There are a few examples of the walls of the abdomen being perforated in consequence of large collections of purulent fluid in its cavity; and we may mention here that perforation of the diaphragm may take place in cases in which similar collections are formed in the cavity of the pleura.

3. Perforation of the walls of the liver, which form the boundaries of an abscess situated in this organ, and of the gall-bladder, may with propriety be noticed in this place. Perforation of the former, with effusion of the contents of the abscess into the cavity of the abdomen, is by no means common, because of adhesion taking place, previous to the occurrence of this accident, between the peritoneum covering the abscess, and that of the stomach, colon, walls of the abdomen, or diaphragm. Under these circumstances, however, the perforation may afterwards extend to the hollow organs we have named, and establish a communication between them and the cavity of the abscess, by means of which its contents are evacuated by vomiting or by stool. A communication between the abscess and the external surface of the abdominal parietes where they cover the abscess, is more common than the former. When the diaphragm adheres to the abscess, and is perforated, three consequences may follow:—the contents of the abscess may pass into the cavity of the chest; into the bronchi, from a portion of the lung which had adhered to the diaphragm having been destroyed by ulceration or sloughing; or into the cavity of the chest and bronchi at the same time. We have seen only one case of the last variety of perforation of abscess of the liver, or, more correctly speaking, of a purulent cyst containing a great number of hydatids. Although these vesicular animals have sometimes been expectorated in cases of this kind, such did not happen in the case to which we allude. The communication between the bronchi and cyst took place first, followed by a yellow-coloured expectoration, which, because of the existence of the cyst in the liver having previously been detected, was supposed to be owing to the passage of the bile into the bronchi from perforation. Soon afterward, symptoms of pleurisy manifested themselves, accompanied with those of effusion and pneumothorax, the real nature of which was not understood till after death. Only one opening was found in the diaphragm, where it covered a cyst from six to seven inches in diameter, containing a yellow, puriform fluid and hydatids. This opening, sufficiently large to admit the fore-finger, communicated with an excavation formed in the inferior lobe of the lung, which adhered but slightly to the diaphragm. In the bottom of this excavation there were several openings, some of them, which were small, communicating with the bronchi, others larger, leading into the cavity of the pleura. This cavity contained a quantity of air, yellow sero-purulent fluid, and a great number of large and small hydatids. The lung was considerably compressed, and the pleura covered with recent coagulable lymph.

Perforation of the gall-bladder occurs rarely except when biliary concretions, of considerable size, are lodged within it. In such cases the preternatural communication generally takes place between this organ and the ascending or transverse portion of the colon, through which these concretions pass into this intestine, and are voided by stool. A similar mode of transmission is afforded them when they are enclosed in the ductus communis choledochus. Their transit from either of these situations into the intestine may be accompanied with violent paroxysms of pain, or no pain at all; a difference which is not easily explained. In one case, in which the pain was extremely severe, and which terminated fatally, we found the duodenum perforated in four or five points near the pylorus, and communicating with the gall-bladder, which contained two large concretions. In two other cases, on the contrary, from the history of which we could not learn that the patients had ever suffered from any of those symptoms attributed to the passage of gall-stones, and who died of diseases unconnected with any derangement of the hepatic organs, we found in one of them a communication existing between the gall-bladder and the colon, in which a concretion was lodged and projecting into the latter, the mucous membrane and other coats of this intestine being quite healthy. In the other case there existed a similar communication, presenting the character of a fistulous passage (for it was lined with a mucous membrane), about half an inch in length, into which a small probe only could be passed. The gall-bladder was empty and greatly atrophiated in both cases, the natural consequence of the cessation of its function. Perforation of the gall-bladder from ulcera-

tion is not common. The only case worth noticing which has come under our observation, was one in which double perforation took place from ulceration of the walls of this organ. One of the perforations was situated towards the free surface of the gall-bladder, and was prevented from communicating with the cavity of the abdomen by the adhesion of a portion of the epiploon: the other was formed where this organ is in contact with the liver, so that the bile was effused between them, and had formed for itself a cavity of considerable size, covered superiorly only by the peritoneum, which rose above the surface of the liver. On this account it could be felt through the parietes of the abdomen, accompanied with the sensation of fluctuation, circumstances which led the physician to diagnosticate the existence of an abscess of the liver. Caustic potash was applied preparatory to laying it open, but the patient died two days after, before this plan of treatment could be carried into effect.

II. Perforation of the Respiratory Organs.—As perforation of the bronchi and pleura will be described in the articles Pleurisy and Pneumothorax, and as a description of it produced by mortification has already been given under that head, we shall only mention a few facts, with regard chiefly to the comparative frequency of its occurrence in the tubercular diseases to which the lungs and some of the neighbouring organs are subject.

The presence of tuberculous matter in the lungs is by far the most frequent cause of perforation of the pleura or bronchi, both of which it destroys within a limited extent, by means of the ulceration or mortification which its presence occasions. It is only when situated beneath the pleura that the tuberculous matter gives rise to a communication between the cavity of this membrane and the bronchi, or when a tubercular excavation occupies the same situation. The escape of the air into the cavity of the pleura is not always the consequence of perforation of this membrane and of the bronchi. We have already stated that the opening in the former is sometimes closed by adhesion of the pleura, and by accidental serous or cellular tissues, which consequently prevents the air or other fluids from passing into the cavity of the chest. It is in this way that perforation of the thorax takes place, and that a communication is established between the surface of the body and the bronchi, through which the air enters and escapes. But should the perforation take place in the mediastinum and bronchi, the inspired air is effused into the cellular tissue included within the former, whence it passes to that of the neck, face, and chest, and may produce extensive and distressing subcutaneous emphysema.

Perforation of the bronchi without perforation of the pleura is a much more frequent occurrence than the former, in whatever part of the lung the tuberculous matter may have been deposited. In this case the bronchi may be simply perforated, or perforated and communicating with a tubercular excavation. Perforation of the bronchi is not an unfrequent consequence of the accumulation of tuberculous matter in the bronchial glands, or the presence of cretaceous matter in these bodies. The former occurs in young persons, and especially in children: the latter sometimes in middle-aged persons, but most frequently in those advanced in life.

This kind of perforation may sometimes be detected during life, from the presence of considerable masses of tuberculous matter or concretions in the sputa. Perforation of the bronchi from the latter cause undergoes sometimes a cure, from obliteration or cicatrization.

The most fatal kind of perforation of the bronchi is that which is accompanied by perforation of a large branch of the pulmonary artery. This complication takes place in two ways:—first, a large bronchus, most frequently the first or second branch of the trachea, and a corresponding branch of the pulmonary artery, are perforated by a tuberculated bronchial gland situated between them. In this case a direct communication is formed between the blood-vessel and bronchus, and the hemorrhage which ensues is so great and rapid, that the blood is thrown forth as if vomited, sometimes by the nose as well as the mouth, and may terminate fatally in from ten to twenty minutes; secondly, a tubercular excavation with which several bronchi communicate, extends in the direction of the pulmonary artery or one of its principal branches to which it adheres. The corresponding portions of the walls of the artery and those of the excavation ulcerate or slough, and hemorrhage takes place, first into the excavation, and afterwards into the bronchi. It is on account of this indirect communication between the perforated vessels and bronchi that hemorrhage in cases of this kind is generally small at first, diminishes and increases at irregular intervals, and sometimes continues for several days.

Perforation of the pleura from abscess, and the effusion of blood under the pleura in pulmonary apoplexy, are not common. In the cases which we have seen of the latter kind, the pleura appeared to have sloughed because of its having been separated from the cellular tissue by the effused blood.

Chronic pleurisy with effusion sometimes terminates in perforation of the walls of the chest or diaphragm; and there are examples of fluid making its way into the bronchi, whence it was expectorated, and the disease terminating favourably.

For perforation of the bronchi and trachea from aneurism, see Aneurism of the Aorta.

III. Perforation of the Organs of Generation.—Perforation of these organs in the female, after the middle period of life, is very common, and, in the great majority of cases, in consequence of cancer. Cancer of the uterus and vagina may give rise to perforation of the walls of both, and a communication be established between them and the following organs: between them and the bladder, or rectum separately, or between them and both of these organs at the same time. Hence the urine, fæcal matter, or both, may be passed in greater or less quantity by the vagina, and sometimes the latter makes its way also into the bladder.

Perforation of the posterior walls of the neck of the uterus or upper portion of the vagina, is not unfrequently followed by perforation of the

peritoneum, and as the progress of the disease upwards is generally accompanied with sloughing of the cellular tissue behind this membrane and the neck of the uterus, a putrid sanies is poured into the cavity of the former, which gives rise to peritonitis, rarely less violent than that which is occasioned by the presence of fæcal matter. Perforation of the peritoneum is sometimes arrested by the adhesion of a portion of small intestine, which may either remain entire, or afterwards become perforated. The latter is the more frequent occurrence.

Caries and necrosis of the bones of the sacrum may give rise to perforation of the upper part of the vagina, from the ulceration and sloughing of the cellular tissue situated between them extending to the latter organ. Such a case may readily be confounded with perforation from cancer.

Perforation of the ovaries and Fallopian tubes seldom occurs. We have met with it in one of the latter, between which and the rectum there existed a communication, through which a purulent fluid, the contents of the tube, escaped, and was passed by the anus. In another case, in which the left ovary was transformed into a purulent cyst, similar consequences followed. Both patients died of other and complicated disease of the uterus. In another case, a communication existed between the left Fallopian tube and ovary. The ovary formed a cyst as large as the two fists; the Fallopian tube was from an inch to two inches in diameter, and both were filled with a sero-purulent fluid, none of which, however, appeared to have passed into the cavity of the uterus. For further information on this subject, see DISEASES OF THE UTERUS AND OVARIES.

IV. PERFORATION OF THE URINARY ORGANS.—1. Perforation of the bladder occurs most frequently in the female, and from the extension of cancer of the uterus, to which we have already alluded. It is also occasioned by ulceration or sloughing in consequence of pressure during pregnancy or delivery; chiefly in deformity of the bones of the pelvis, or from the improper use of instruments when employed to extract the fœtus.

In the male it is more often occasioned by the catheter left in the bladder in cases of paralysis of this organ, and in stricture of the urethra in old men, than by any other cause. The perforation is generally the consequence of sloughing of the walls of the bladder which were in contact with the point of the catheter.

2. Perforation of the walls of the kidneys seldom occurs. When it happens, the loose cellular tissue with which these organs are so abundantly surrounded, becomes the seat of abscess. In one case of this kind which we examined, a small abscess was situated between the kidney and descending colon, and communicated with the cavity of this intestine. In another, an abscess containing several pints of pus, and situated between the kidney, descending colon, and lateral walls of the abdomen, likewise communicated with this intestine. The quantity of pus passed by stool in the latter case was considerable. The substance of the kidney was almost entirely occupied with tuberculous matter, as well as the infundibula and pelvis. In the former, the pelvis of the kidney contained a large calculus, and its substance was converted into a firm uniformly grey tissue. Both cases terminated fatally. The patient, a female, in whom the former case occurred, was about twenty years of age; the other was a man above fifty.

V. PERFORATION OF THE ORGANS OF CIRCULATION.—Perforation of these organs may be considered as it occurs in the heart, arteries, and veins. The occurrence of this lesion in the arteries is infinitely more frequent than in the heart or veins, owing obviously to their being subject to diseases which rarely affect the latter, as well as to the impulse of the blood, and the distension occasioned by this fluid propelled into them by the heart: thus perforation of the arteries, in the great majority of cases, takes place in consequence of the deposition of a substance resembling bone, chalk, or putty, which often destroys their walls, or deprives them of their elasticity. In the first case, the internal and middle coats may be perforated without their having undergone any previous change of capacity, so that the cellular coat, being brought in contact with the blood, is pushed outwards by this fluid, and forms what is termed *circumscribed false aneurism*. In the second case, the internal and middle coats being deprived of their elasticity by the presence of one or other of these substances we have named while yet in a fluid state, yield to the continued impulse of the blood, and ultimately form a sac or pouch of various dimensions, occupying either a portion or the whole of the circumference of the artery, and which, under these circumstances, constitutes what are commonly called *circumscribed* and *diffuse true aneurism*. Perforation of the dilated coats of the artery takes place at a subsequent period, first in the internal and middle, and afterwards in the cellular. In whichever of these ways the aneurism is produced, perforation of the cellular or outer coat of the sac may take place under the two following circumstances;—first, when the surface of the aneurism is free from adhesion with a neighbouring organ, as sometimes happens when it is lodged in the thorax or abdomen, when the blood is poured into the serous cavity of either of these parts of the body; secondly, after the aneurism has become united with a neighbouring hollow organ, or the walls of the cavity in which it is contained, when, after the perforation of either of these, the blood is effused either directly on the surface of the body, or escapes by one of the natural passages, for example, the œsophagus or trachea.

Perforation of the arteries (we speak of the larger branches or trunks) is not unfrequently the consequence of ulceration proceeding from without inwards. When this happens, the ulceration may take place originally in the walls of the artery which becomes perforated; or in a portion of an organ in the immediate vicinity of an artery, to which it afterwards extends, producing a solution of continuity of its walls. We have already given examples of perforation of the former kind in the case of tuberculated bronchial glands; and examples of the latter are met with in several organs, and particularly in the stomach in some cases of chronic ulcers, in which one of the coronary arteries of a large branch happens to traverse the bottom of such an ulcer, and becomes perforated by the ulcerative process.

When cancer produces perforation of an artery, it is, in general, owing more to the walls of the vessel having been destroyed by the extension of this disease to them than by ulceration. The same is the case in perforation of veins from a similar cause. These vessels are not so often perforated by ulceration as the arteries, and the hemorrhage is seldom great unless they are considerably dilated, as in hemorrhoids; or their walls much thickened and united with indurated cellular tissue, which prevents them from collapsing, as sometimes happens in the case of chronic ulcers of the inferior extremities, accompanied with varicose dilatation of the veins. In a case of this kind which we had occasion to examine, the hemorrhage which followed the perforation of the vein was so great that the patient, a man about forty years of age, expired in little more than ten minutes.

There are a considerable number of examples of perforation, more commonly termed *rupture*, of the heart. The portion of this organ the most subject to this lesion is the inferior and middle portion of the left ventricle. Sometimes softening or ulceration, at other times atrophy of the muscular substance in the situation of the perforation, are the lesions which are found to precede the occurrence of this accident; at the same time, the walls of the ventricle are, in general, more or less hypertrophiated.

There may be one, two, or three perforations which traverse the walls of the ventricle either perpendicularly or obliquely. In the latter case the hemorrhage which ensues does not, it is said, prove so suddenly fatal as in the former case. It does not appear that the *quantity* of blood effused bears a necessary relation to the length of time that supervenes before death takes place.

We have no certain evidence to show that perforation of the heart is curable, although Rostan relates a case in which he conceived he saw the cicatrix of a perforation of the left ventricle in a patient, who was supposed to have presented the symptoms of this lesion some time before her death, which was occasioned by a second perforation.

Perforation of the valves of the heart is seldom observed except in those of the aorta, and in the cases which we have seen, it appeared to be the consequence of the presence of osseous or cretaceous matter deposited in their substance or between their laminæ.

VI. Perforation of Hollow Bones occurs in cancerous affections of their walls, and when pus or hydatids are contained within them. The latter generally produce perforation by exciting inflammation and caries of the bone; the former, by the gradual transformation of a portion or the whole circumference of the bone into a lardaceous or cerebriform substance. In this case, fracture more frequently takes place than perforation of the bone.

VII. Perforation of the Eye. — The cornea is that part of the eye which is most frequently perforated. It may be in consequence of ulceration or sloughing, accompanied or not by similar diseased states of the other tunics of the eye; by an accumulation of pus, or the presence of malignant tumours proceeding from within outwards. (See Ophthalmia.)

VIII. Perforation of the Ear. — Perforation of the membrane of the tympanum is not very rare in severe cases of inflammation of the internal ear terminating in suppuration. The solution of continuity of the membrane, which follows the accumulation of the pus in the cavity of the tympanum, may be the consequence of ulceration or sloughing, favoured by the mechanical distension to which it is at the same time subjected. So soon as the perforation is completed, a sudden and copious discharge of puriform fluid makes its appearance, and which, if there has been no discharge before from the external orifice of the ear, may be regarded as a certain sign of its coming from the cavity of the tympanum in consequence of perforation of its membrane.

The effects of perforation of the tympanum on the function of hearing depend on the size and situation of the artificial opening, and the degree of integrity of the *ossicula* with which this membrane is connected. Suppurative inflammation of the bony structures of the internal ear may produce in a similar manner perforation of the *membrana tympani*, as well as accidental products developed in the same situation.

R. Carswell.

PERICARDITIS. — I. Of Pericarditis. — The anatomical characters of acute inflammation of the pericardium are, 1, preternatural redness of the membrane; 2, coagulable lymph, adhering to its surface; and 3, fluid effused within its cavity. These characters we shall treat of in succession, and at some length; for as the anatomical characters are the key to the symptoms, the latter cannot be understood, and, consequently, so rapid and fatal a malady cannot be treated with the promptitude and decision essential to the safety of the patient, unless the nature of the former and their intimate connection with the symptoms are thoroughly known to the practitioner.

1. *Preternatural redness of the pericardium.* — The redness very seldom pervades the whole of the inflamed portion. It presents itself sometimes in numerous small scarlet specks, with a natural colour of the intervening membrane, sometimes in spots of greater or less magnitude formed by the agglomeration of the specks, and sometimes in patches of considerable extent. Even these, however, have, almost without exception, a dotted or mottled character. In some cases, according to Laennec, though the inflammation, judging of it by the thickness of the false membranes, had been very severe, scarcely any redness exists. Vascular injection of an arborescent and sometimes stellated appearance, accompanies redness, and is generally proportionate to it in degree. Occasionally, however, the redness is uniform, like a stain.

The pericardium is very rarely, if ever thickened; that which is often regarded as thickening being nothing more than superimposed and intimately adherent false membrane.

When acute pericarditis degenerates into chronic, the redness loses its brilliancy, sometimes becoming very deep and of a brownish colour,

and sometimes acquiring a cinnamon hue. Beneath a layer of lymph of this colour, we have seen the surface of the heart of a bluish-white appearance, like the spots so frequently found on this organ.

Redness alone does not afford conclusive evidence of pericarditis, as all serous as well as mucous membranes are liable to vascular injection from various causes independent of inflammation. To afford such evidence, therefore, the redness must be conjoined with an effusion of lymph or sero-purulent fluid.

2. *Coagulable lymph adhering to the surface of the Pericardium.*—The inflamed pericardium secretes serum and lymph conjointly, and in a fluid state, from the same vessels. Soon after the secretion has taken place, the lymph concretes, while the serum remains fluid. The former, when recent, is of a pale straw-colour, and of a soft tender consistence, becoming firmer and more tenacious as it grows older. Though occasionally deposited in detached lumps and specks, it generally forms continuous layers, sometimes covering a portion only, but more commonly the whole, or nearly the whole, of the pericardium. The thickness of the deposition may vary from a line to an inch; but from a line and a half to three lines is its ordinary mean. Its adherent surface is smooth; the opposite or free is rough and singularly figured. It is sometimes pitted with small depressions at tolerably regular intervals, presenting the aspect of a fine reticulation, or of the section of a sponge. This occurs principally where the layer is thin: where it is thick, the surface is distributed into more spacious cells, often as large as a pea, and separated by coarser partitions. The partitions are sometimes irregular, being higher and thicker in one part than another, in which case the effect is exactly that produced by separating two flat plates between the surfaces of which a layer of soft butter has been spread. At other times the partitions are very regular; in which case the appearance, as Corvisart observes, is analogous to that of the second stomach of a calf. Occasionally they are very thick and rounded, and then they have an appearance somewhat similar to that of a congeries of small earthworms. Not unfrequently they are shaggy and flocculent, hanging in shreds like tow. Sometimes no cells are apparent, but the lymph is arranged in transverse, and, as it were, plaited wrinkles, like undulations of sand on the seashore. When lymph becomes old, and not adherent, it acquires a deeper hue, varying from cinnamon to an intense brown-red or mahogany colour. When of the latter colour, it usually secretes bloody fluid.

Now, what is the object which nature proposed to herself in the effusion of lymph? Unquestionably to effect reparation—the object for which the effusion is designed in whatever part of the system it takes place. But how, it may be inquired, can it effect reparation in the pericardium? By causing adhesion. Supposing that the inflammatory process does not terminate by resolution—by the complete absorption of both lymph and serum, the most desirable termination which remains is adhesion; for should this not take place, the lymph becomes a secreting surface, which effuses more and more lymph and serum, until in a short time the cavity is completely distended, and the action of the heart so embarrassed that a fatal termination speedily ensues. But, should adhesion of the opposite surfaces take place, by which further effusion is prevented, life may be prolonged for a considerable period, even for years; though, as will presently be explained, the adhesion, so far from being a perfect reparation, gives rise to another form of organic disease, which eventually proves destructive to the patient.

Adhesion takes place in some cases and not in others,—a circumstance which has been attributed to a difference in the quality of the lymph, dependent on the greater or less energy of the inflammation, in consequence of which it possesses different degrees of aptitude for adhesion. This explanation, though perhaps not unsound, is scarcely applicable to the pericardium; for here the union or non-union depends mainly on the absence or presence of fluid in the cavity: the best lymph, equally with the worst, being incapable of uniting when interposed fluid prevents the apposition of the opposite surface. Hence it is that the upper part of the pericardium, where it is reflected from the great vessels, often adheres when the lower part does not: and for the same reason it is that, when the whole of the peritoneum is covered with lymph, the intestines adhere to each other, but their adhesion with the walls of the abdomen is prevented by the interposition of fluid.

Hence the immense importance in pericarditis, of prompt and energetic treatment in the first instance, in order, if resolution cannot be effected, to cause absorption of the fluid, and thus afford the opportunity for adhesion. Temporising indecision is inadmissible; for unless one or other of these terminations be induced, the patient inevitably dies.

Such is the object of adhesion: we have now to describe the process. When the fluid has been sufficiently absorbed, the depositions of lymph on the opposite surfaces of the pericardium come in contact, thicken, blend, and gradually become organized by vessels presenting themselves under the successive appearances of blood-stains, straggling lines, and, lastly, of uniform pinkish vascularity, susceptible of injection from the pericardium. The depositions are thus converted into perfect cellular tissue, by which the contiguous parts are more or less firmly, closely, and extensively agglutinated. When adhesion is of recent standing, the lymph is generally thick, and separable by mere tearing into two layers, one adhering to each fold of the pericardium. In proportion as the disease is older, the false membrane is thinner and firmer, consisting, in cases that date several years back, of the finest layer of dense cellular tissue. In some, even this is not perceptible, the folds of the pericardium having become amalgamated—apparently without the intervention of any membrane,—so as with difficulty to be separable, even by the scalpel. It is in such cases that pathologists have sometimes erroneously supposed the heart to be destitute of a pericardium.

In some rather protracted cases, generally of at least two or three months' duration, where, though

adhesion has been established, inflammation has either recurred or never been completely subdued, an additional interstitial deposition of lymph takes place, which has been known to thicken the adventitious mass to the extent of an inch and upwards. In this case it sometimes possesses a laminated texture, the layers of which are progressively redder in proportion as they are nearer the heart; and sometimes it exhibits different degrees of consistence in different parts, one being almost liquid and purulent, while another has the density of tubercular induration. (*Latham*, Lond. Med. Gaz. vol. iii. p. 5.) Such cases are ordinarily fatal at no very remote period.

But adhesions are not always universal; in cases of partial pericarditis they are restricted to the portions inflamed; and when these portions are limited, the adhesions are not close or intimate; for as the gliding motion of the heart within the pericardium is not prevented, it stretches the adherent lymph, and converts it into long loose bands of cellular tissue. But when the portions inflamed are extensive, partial adhesions are sometimes close and firm, and the intervening parts of the pericardium may be healthy and in contact. Instances occasionally occur of adhesions being partial though the inflammation had been universal; and the parts not united are overspread with lymph and separated by purulent fluid, thus constituting a series of small, detached abscesses around the heart.

Cases of partial pericarditis (exclusive of white spots, of which we shall presently speak) are very rare in proportion to those of general, scarcely amounting, according to Laennec, to one in ten. (De l'Auscult. Med. tom. iii. p. 655.) They almost always terminate in recovery, and the adhesions, if loose and long, seldom lead to enlargement of the heart.

Partial pericarditis sometimes leaves no other vestiges than opaque white or milky spots, which are a well-known appearance on the surface of the heart. They vary in extent from a few lines to two or three inches in diameter; their thickness is about that of the nail: they consist of condensed cellular tissue, and with a little care they may generally be detached without injury to the pericardium beneath. This membrane is commonly somewhat injected, though not thickened.

Sometimes lymph is converted into small, roundish, soft granulations, like concrete albumen, with which the pericardium is more or less extensively studded.

3. *Fluid effused within the cavity of the Pericardium.*—It has been stated that serum is effused conjointly with lymph, from the vessels of the inflamed pericardium. This fluid is sometimes transparent, and either of a faint yellow, more or less tinged with green, like that of the interior of a lemon, or of a pale fawn colour; at other times it is less transparent, but very seldom milky or opaque from containing particles, filaments, or flakes of imperfectly concrete albumen. Its quantity, though variable, is in general considerable at the commencement, that is, within the first two, three, or four days of the disease, — not unfrequently amounting to more than a pint. Corvisart once found four. It is speedily diminished, however, by absorption, when the first violence of the inflammation begins to subside; and after the lapse of a few days it is, in the majority of cases, not more abundant than the concomitant exudation of lymph. Sometimes, indeed, even in very acute inflammation, the absorption is so complete that no serum whatever is found, while a copious exudation of thick concrete lymph fills and agglutinates the whole cavity.

Should complete absorption of both the fluid and lymph not take place, nor yet adhesion of the pericardium be established, the fluid presently assumes a very different character. For it is no longer secreted by the pericardium, but by the lymph itself, which, when organized, becomes a secreting surface; and its secretion, though at first consisting of clear serum, gradually becomes more and more turbid, milky, and opaque, until it eventually assumes the character of pus. Rarely, however, is perfect pus found in the pericardium; probably because the patient dies from irritation before the suppurative process is fully established. Not unfrequently the fluid is bloody, and the lymph of a red colour. This is attributable to the tenderness of all newly organized structures, in consequence of which they are apt to become congested, and to effuse blood when subjected to any unusual irritation or excitement. The excitement in the present instance most probably consists in inflammation of the adventitious membrane, either renewed, or never wholly suspended.

Compression, exercised by fluid, and even by great accumulations of lymph, sometimes reduces the volume of the heart, and renders it atrophous.

Such are the anatomical characters of acute pericarditis, both in its early and its advanced stages. It remains to make a few remarks on that form of pericarditis which appears, from the mildness of the inflammatory symptoms, to have been chronic from the first. Its anatomical characters do not differ very materially from those exhibited by the advanced stages of the acute form. The inflammation always pervades the whole of the cavity; the redness is deeper and duller than in the acute affection; the albuminous false membranes are, in many cases, totally deficient, and when present, they are thin, soft, and fragile, as if wasted by suppuration: finally, there is always a more or less abundant effusion of turbid, milky, and sometimes completely puriform fluid. *Intimate* adhesions of the pericardium to the heart may follow the absorption of this fluid; but M. Laennec does not appear to be borne out either by facts or by analogy, when he supposes that chronic pericarditis alone is the cause of intimate adhesion, and that the acute affection only gives rise to loose adhesion by more or less elongated bands. According to our experience, the latter is the more frequent cause of intimate adhesion.

The muscular substance of the heart is, in general, not affected by pericarditis; but sometimes it is rendered redder or paler, browner or yellower, harder, softer, or more lacerable, than natural. These changes result from inflammation propagated from the pericardium to the muscular substance. They will be more fully considered in the article Carditis.

In scrofulous and phthisical individuals, tuber

cles are sometimes developed in the false membranes of pericarditis, and, according to Laennec, they may cause the acute to pass into the chronic state, as frequently happens in the case of pleuritic and peritoneal false membranes.

Signs and Diagnosis of Pericarditis.

General signs.—There is no inflammatory affection of which the diagnosis has been considered more difficult than pericarditis. Laennec states that he has often, on dissection, discovered the disease, in a severe form, when nothing had afforded a suspicion of its existence; and, on the other hand, that he has frequently witnessed all its signs without finding a vestige of the malady. Dr. Latham mentions two cases of what appeared to be, and was treated as, marked inflammation of the brain; yet this organ was found perfectly sound, and the heart affected with intense pericarditis. (Lond. Med. Gaz. vol. iii. p. 209.) Andral relates a similar case. (Clinique Médicale, vol. iii. p. 444.) It is proper to keep these difficulties prominently in view, in order that practitioners may be better prepared to contend with them. But it must be added that such cases as those of Latham and Andral are extremely rare; and that, with the improvements in diagnosis introduced by modern research, the disease may, we feel assured from numerous post-mortem examinations, be nearly always detected. We shall first enumerate the symptoms, and then endeavour to point out the causes of their obscurity, the means of rendering them available, and the diagnosis from other inflammatory affections.

The symptoms are as follows; acute inflammatory fever; a pungent, burning, lancinating pain in the region of the heart, shooting to the left scapula, shoulder, and upper arm, but rarely descending below the elbow, or even quite to it. The pain is increased by full inspiration, by stretching the left side, and especially by pressure between the præcordial ribs, and by forcing the epigastrium upwards underneath the left hypochondrium. When the inflammation is only subacute, the pain is more or less dull, and does not lancinate. The next symptoms are, inability of lying on the left side, and sometimes in any position but one, which is most commonly on the back; [the writer has often observed the incapacity of lying on the left side to be wanting;] dry cough; hurried respiration; palpitation of the heart, the impulse of which is sometimes violent, bounding and regular, though its beats may at the same time be unequal in strength; at other times it is feeble, fluttering, and irregular; pulse always frequent, and generally, at the onset, full, hard, jerking, and often with a thrill. Sometimes it maintains these characters throughout, but more commonly it becomes, after a few days, weaker than accords with the strength of the heart's action, and, in the worst cases, small, feeble, intermittent, irregular, and unequal. Occasionally it possesses the latter characters from the commencement; whenever they exist, they are accompanied by dyspnœa; a constrained position, deviation from which induces a feeling of suffocation; extreme anxiety; a peculiar drawn or contracted appearance of the features, occasionally with the sardonic grin; faintness, constant jactitation, insupportable distress and alarm, cold perspiration, and, finally, from obstruction of the circulation, by intumescence and lividity of the face and extremities.*

One cause of the obscurity of the above symptoms would, at first sight, appear to consist in their diversified, incongruous, and variable nature. The pulse, for instance, displays, at one time or other, almost every kind of character; the disease, though the inflammation be equally intense, is sometimes very supportable—at others, agonizing; in one case it terminates fatally in two or three days, in another it lasts as many weeks.

Now, in reality, these diversities, while they do not render the symptoms less pathognomonic of the disease in general, as will presently be shown, are invaluable indications in another point of view—they denote the nature and progress of the anatomical changes of structure, and, in correspondence, the progress and exact state of the malady. For it is ascertained by experience that a difference in the quality and quantity of the effusion imparts a totally different aspect to the symptoms. Thus, when, either from the effusion consisting principally of concrete lymph, or from the simultaneously secreted serum being absorbed, universal adhesion of the pericardium promptly takes place, preventing all further fluid effusion, the action of the heart maintains throughout much the same vigour and regularity as it manifested at the onset of the malady, and the pulse exhibits corresponding characters of strength, hardness, and regularity. Under these circumstances, also, the position is less constrained, and less pain is produced by an unfavourable one; in consequence, perhaps, of the heart being curbed by the adhesion, and thus prevented from impinging with the same degree of violence against the thoracic walls. Finally, as the force and rhythm of the heart's action, and consequently the circulation, are adequately maintained, the life of the patient will be prolonged probably for weeks, even though the inflammation remain unsubdued, and he will sink, at last, apparently from mere exhaustion by the effects of protracted irritation.

But should there be a copious serous effusion, the heart's action is mechanically embarrassed by the compression that the fluid occasions,—a compression which is the more considerable because the pericardium, deprived of its distensibility by inflammation, is incapable of yielding as the fluid accumulates. Hence the organ, unable to transmit its contents, becomes congested: it flutters, intermits, beats feebly, irregularly and unequally. The pulse has corresponding characters, and is sometimes scarcely perceptible. Hence supervene faintness, dyspnœa, anxiety, coldness, lividity, a sense of suffocation on the slightest deviation from a certain position, with all the other symptoms indicative of an obstructed circulation. If this state be not expeditiously relieved by remedies, the patient dies in the space of a few days, or even hours.

Should the fluid be copious from the first, this series of symptoms will make its appearance equally early; but in general, two or three days elapse before the accumulation becomes considerable; in which case the former series will exist during this period, and will then be suddenly replaced by the latter. In a few instances we have

* We have seen extensive œdema of the feet supervene during the last twelve hours of life.

found the latter exist when the quantity of fluid was inconsiderable, but that of lymph enormous. We conceive, therefore, that an enormous accumulation of lymph has the same effect as fluid in embarrassing the action of the heart. We have also found the worst class of symptoms occasioned by a less quantity of fluid in some cases than in others,—a difference which probably depends in some instances on diversities in the nervous irritability; but in others we suspect that it is connected with the coexistence of carditis; for, when the affection has been thus complicated, we have known the feeble, fluttering action of the heart and all its concomitant train of unfavourable symptoms, occur, though the effusion within the pericardium was inconsiderable. The peculiar expression of the features is occasioned by the sympathy subsisting between the respiratory nerves of the face and those of the heart.

Such are the causes of the symptoms. It will now be apparent that their variability is calculated to enlighten rather than to perplex the practitioner; and that, whatever aspect they assume, they would still be abundantly sufficient, did no other difficulties interfere, to render the disease one of easy diagnosis. But unfortunately there are other difficulties. Some of these consist in the absence or mildness of certain of the most important symptoms.

When pain in the immediate situation of the heart, increased by pressure in the interspaces between the ribs, or upwards under the left hypochondrium, is accompanied by increased action of the organ and by fever, there can scarcely be a doubt of the existence of pericarditis. But sometimes, though rarely, pain is totally absent; in which case the practitioner must carefully employ pressure, as above directed; and if, notwithstanding, no pain be felt by the patient, he must carefully turn his attention to the remaining symptoms. Should the pulse be feeble, faltering, intermittent, unequal, &c., without any apparent adequate cause, (and it is well known to practical men that such a pulse rarely if ever exists in ordinary cases without a discoverable cause,) this sign,* especially if attended with the usually concomitant signs of an obstructed circulation, affords evidence of the strongest description.

But there may be neither pain nor an unsteady pulse. In this case, should the action of the heart be violent, and of a remarkably bounding or jerking nature, without any manifest cause,—especially organic disease of the organ; and should it be accompanied by a greater degree of fever and anxiety than can be accounted for by any other existing complaint; finally, should it be attended with the stethoscopic signs presently to be described, the physician will seldom be wrong in diagnosticating pericarditis. The presumption is still stronger if, when the symptoms supervene, the patient is affected with acute or subacute rheumatism,—an affection which, whether severe or mild, whether in its early or its later stages, is beyond comparison the most frequent cause of pericarditis.

It was an opinion of Corvisart that the most acute cases were the most obscure, because, says he, "the attack is abrupt, the progress rapid and the termination always sudden." This obscurity was felt by that acute observer because he was not acquainted with any signs of the disease on which he could depend but the feeble, unsteady pulse the anxiety, dyspnœa, lividity, and other symptoms dependent on obstruction of the circulation,—symptoms which did not always show themselves early enough to afford him data for the diagnosis before the case was hopeless. At present, however, when we are in possession of so many signs, the same obscurity does not exist. We have seldom experienced, nor have we seen other physicians experience, much difficulty in recognising the acute pericarditis to which Corvisart refers. The most obscure cases are those mentioned by Latham and Andral, in which an inflammation of the brain or any other organ diverts the attention from the heart, and the delirium of the patient renders it impossible to obtain information from himself. Still, when apprised that such cases exist, we should think it perhaps not impossible to provide against them. If, for instance, it were the general practice, (one which we invariably pursue,) to place the hand on the præcordial region as well as on the pulse in every severe inflammatory or febrile affection, in the same way that we daily feel the abdomen in cases of fever, even though the patient make no complaint of it, we should seldom fail to find an inordinately increased impulse or some other anomaly in the action of the heart, which would lead us to make a regular and probably successful investigation for pericarditis. For there can be little doubt that the symptoms in the cases alluded to, are in reality not absent but merely masked by others of predominant severity. Such an investigation is especially necessary in young children, who cannot explain their sensations, and seldom give indications of the existence even of acute pain.

The only remaining cause of obscurity is, inflammation of some of the thoracic viscera, particularly the pleura, the pain of which may be seated over the heart. Pleurisy may be detected by ægophony, extensive dulness on percussion, and diminished or absent respiratory murmur. Peripneumony may, in addition to its ordinary symptoms, be recognised by the crepitous rhonchus, deficient respiratory murmur, and dulness on percussion; finally, bronchitis may be known by the mucous, sibilous, and sonorous rhonchi. Should none of these signs be present, the negative evidence thus obtained fixes the disease on the heart; but should they be present, the diagnosis of the pericarditis must be made by a general comparison and cautious consideration of all the symptoms. In this case, should the affection of the heart be overlooked, the error is not one of the most serious kind, as the treatment for pleuritis or peripneumony is well adapted for pericarditis.

In a disease the treatment of which requires so much decision and promptitude in the practitioner as pericarditis, it is necessary for him to be thoroughly conversant, not only with the symptoms of deterioration, but also with those of amelioration. To these, therefore, we shall advert before proceeding to the physical signs.

If the worst symptoms decline, namely, the feeble, fluttering, unsteady pulse, the feeling of

* On it alone we have seen M. Chomel found a successful diagnosis in the last stage of a typhus fever, when the symptoms were extremely complex.

faintness and suffocation, and the constrained position to which that feeling confines the patient, we may be tolerably sure that the fluid, on which these symptoms commonly depend, is decreasing by absorption. But, notwithstanding, should pain, violent impulse, fever, and anxiety continue, the inflammation is in progress, and is adding to the accumulation of lymph, if not also of fluid. Should, however, the pain, instead of being fixed and pungent, become a diffuse uneasiness; should the anxiety decrease, and the peculiar vehemence of the heart's action gradually degenerate into the beat of a merely accelerated circulation, the inflammation may be presumed to be on the decline; but it is not until all these symptoms have completely ceased that it can safely be said to have terminated.

Still, lymph and adhesion of the pericardium may remain, rendering the reparation imperfect; and such we may consider to be the case so long as, with every advantage of perfect tranquillity and abstinence, the motions and sounds of the heart do not completely regain their natural standard. Even though this be regained, nothing is more common than a recurrence of palpitation and other symptoms of diseased heart when the patient resumes his accustomed avocations. It is not, therefore, until, very gradually returning to corporeal exercise, he finds himself, after an adequate trial, perfectly capable of his wonted exertions, that the cure can be pronounced complete.*

Physical Signs. — *The impulse* of the heart is greatly increased,—not only heaving the thoracic walls vigorously, but being remarkable for its abrupt or jerking character; whence it often shakes the whole anterior chest. Some beats are generally stronger than others, even when the action is regular. The pulse or rather throb of the arteries, often perceptible over the whole body, is of a corresponding nature, each undulation of the blood shooting with instantaneous velocity under the finger, as if through a lax or imperfectly filled tube, and constituting what is called a bounding, or, more expressively, a jerking pulse,—the pulse that we feel during reaction after uterine or other excessive hemorrhage. Very frequently it is accompanied with a distinct thrill. Sometimes it is stronger and more voluminous, at others smaller and weaker; yet in the latter case it still retains the same jerking character.

When the action of the heart becomes feeble and faltering, the impulse of the organ of course sustains a corresponding change; but, notwithstanding, the jerk accompanies any isolated contraction that happens to be strong.

An impulse and pulse of the jerking description denote an inordinately abrupt, and as it were spasmodic contraction of the heart, probably attributable to an increase of irritability resulting from the inflammation. It is this peculiarity in the beat which distinguishes it from the beat of a merely accelerated circulation, a distinction perfectly familiar to practical men. The peculiarity subsists not only during the continuance of inflammation, but so long as the action of the heart remains quick after the inflammation has apparently subsided,—a period which generally occupies several weeks, and, if adhesion of the pericardium has taken place, frequently as many months. We have known it exceed half a year. In very protracted cases it is probable that the irritability of the heart is kept up either by an occasional recurrence of inflammatory action, or by the unnatural circumstances in which the organ is placed by adhesion, or, finally, by a softened state of the muscular substance, the result of carditis.

The Sounds. — The sound of the ventricular systole is not unusually sonorous, but is accompanied with a bellows-murmur. This sign was first noticed by Dr. Latham, who pointed it out to us at St. Bartholomew's Hospital in 1826. Since that time we have never found it absent *when the heart presented the increased jerking impulse* above described. Dr. Latham restricts his observation to rheumatic pericarditis: to ourselves the phenomenon has appeared to exist equally in every form of the disease. When the action of the heart has been feeble and faltering, we have found the murmur absent; but when, in the same case, the action has, either previously or subsequently, been strong and jerking, the murmur has existed. The reason of this will be obvious from the explanation which will presently be offered. The murmur sometimes continues after the heart appears to have resumed its natural action and the patient to be well; but so long as it remains, as remarked by Dr. Latham, (Lond. Med. Gaz. vol. iii. p. 214) "his return to the habits and exertions of health will bring back palpitation and other symptoms, which bespeak the certainty of mischief still abiding in the heart.

Not the ventricular systole only, but occasionally, though by no means always, its diastole likewise is attended with the bellows-murmur; and we have found this supersede and as it were annihilate the natural second sound more completely in pericarditis, than, we think, in any other affection of the heart. Sometimes, in short, it is a pure whizzing, as prolonged as, and almost continued into, the first sound. Three cases at present under our care present this character.

What is the proximate cause, and what the mechanism of these preternatural murmurs? That of the ventricular systole we are inclined to attribute, mainly at least, to the increased velocity with which the blood is propelled in consequence of the morbidly abrupt contraction of the heart,—an explanation which appears to us to be rendered probable by the following considerations: 1. by repeated abstractions of blood, in animals, at intervals of a day or two, we have produced at pleasure, the rapid, throbbing, jerking, and thrilling action of the heart and arteries, and, in strict concomitance with it, the bellows-murmur; 2. the murmur takes place in nervous palpitation when the action of the heart and arteries is of the nature described; 3. the loudness of the murmur observes a very accurate ratio to the violence of the throbbing, and it subsides when the throbbing ceases, unless there remain an organic lesion, presently to be described, which generates it on a different principle.

But though we attribute the murmur of the ventricular systole *mainly* to the cause described,

* See an excellent paper by Dr. Latham, Lond. Med. Gaz. vol. iii. p. 213, to whom the profession in general, and ourselves in particular, are greatly indebted for his researches on this subject.

we believe that it may, in some instances, originate partly in another cause; namely, constriction of the arterial orifices consequent on inflammation of the lining membrane. For, as this membrane is more liable to inflammation where it constitutes the valves than elsewhere, it is consistent with analogy to suppose that, by its intumescence and loss of elasticity, the orifices will undergo the constriction alluded to.

The murmur accompanying the second sound we are inclined to attribute perhaps entirely to the same constriction, affecting the auriculo-ventricular orifices. This we infer, because we have not found it produced in any appreciable degree by abrupt, jerking action of the heart in reaction from loss of blood, and in nervous palpitation; and because, when we have noticed it in pericarditis, we have invariably found it connected with a more or less thickened and opaque state of the valves—a state which, though perhaps scarcely amounting in every instance to an obstruction when it was examined in the dead subject, gives sufficient reason to believe that it might have constituted one during the period of acute inflammation. Should this be found true, the bellows murmur of the second sound renders the prognosis more gloomy, as it bespeaks a more extensive inflammation, and the probability of subsequent valvular disease.

[It may admit of question, whether the bellows sound accompanying the contraction or dilatation or both is ever present in simple pericarditis. It probably, in all cases, indicates the co-existence of inflammation of the endocardium,—*endopericarditis.*

The first effect of inflammation of a serous membrane is to diminish, or totally arrest the secretion that takes place from it in health, — hence the sound of rubbing of two dry surfaces upon each other is an evidence of the early stage of pericarditis. A similar sound may, however, be produced by the friction of plastic lymph, which is often copiously exuded after the inflammation has continued for a time. This friction sound is equally heard during the contraction and dilatation of the ventricles, and has been termed the *to-and-fro* sound. This sound has been compared to the rustling of taffetas, bank-note paper, or parchment. When the effusion is considerable,—in addition to extensive dulness on percussion, the sounds of the heart seem to be distant, and, consequently, obscure. This secretion takes place at an early period of the disease, and is occasionally very considerable; the quantity of serum effused in the first three or four days amounting, at times, to ten or fifteen ounces. When the disease terminates in health, this is gradually absorbed. Occasionally, there is an evident tremour over the cardiac region.

Air, it is said, has been found along with the albuminous secretion, but this must be a rare occurrence. Where it exists alone—*pneumo-pericarditis*—it is said to be indicated by remarkable resonance on percussing the region of the heart, —a resonance, which is much greater than when a portion of emphysematous lung is between the chest and the heart. When air is associated with effused fluid, it may be detected by the sound of splashing or of fluctuation heard when the chest is shaken.]

Percussion.—When the pericardium contains much fluid, the resonance of the præcordial region becomes dull over a greater extent than natural. The impulse, also, it may be added, is undulatory, and not exactly coincident with the first sound, in consequence of the heart having to displace the fluid interposed between it and the thoracic walls, before it can impinge against the latter. (See Hydropericardium.) M. Louis states that he has found a temporary effusion of fluid cause a prominence of the cardiac region. We do not happen to have noticed this, but we think it very probable, especially in young subjects, in whom the cartilages are soft.

Signs and Diagnosis of Chronic Pericarditis.

General signs.—The signs of chronic pericarditis are much the same as those of acute, but in a very inferior degree. The fever is more that of hectic or marcor, with occasional exacerbation, when perhaps the inflammation becomes subacute. The anxiety and restlessness, though sometimes great, are comparatively supportable. The position is less constrained, and we have observed that the patient often prefers the sitting posture with the body inclined forwards. The circulation is less embarrassed, and the action of the heart, though often abrupt and jerking, is usually somewhat feeble, except during any temporary exacerbation of inflammatory action. The pulse, also, is sometimes not very unsteady though the pericardium be full of fluid; which we attribute to the elasticity of the membrane not being so far destroyed by the inflammation as to prevent it from gradually undergoing extension, and accommodating itself to its contents, whence compression of the heart by the fluid is in some degree obviated. The patient, we have thought, more frequently complains of a load and fulness, "something which he cannot get down," in the scrobiculus cordis, in chronic than in acute pericarditis.

Chronic pericarditis, especially if such from its commencement, is more obscure than acute. We have, in former years, seen it overlooked more than once. But these cases, when we now revert to them, appear to us to have presented sufficiently characteristic symptoms. The history affords the greatest light. If the patient, previously exempt from disease of the heart, has suddenly become affected with its symptoms, attended by marcor and some degree of fever, within a period seldom extending beyond a few months, and which he often dates from a blow or fall on the breast, a rheumatic fever, or an inflammation with pain in the præcordial region, chronic pericarditis may be strongly presumed; and if these symptoms coincide with the physical signs of fluid in the pericardium, the existence of the malady may be regarded as almost certain.

Physical signs.—The impulse and pulse have much the same general characters as in acute pericarditis, except that, as the heart's action is less vigorous, they are not so strong.* The signs of

* The sounds will vary according to circumstances. When the action of the heart is jerking, and not wholly devoid of force, the first sound will be attended with a murmur, which, however, is generally very slight. When

fluid in the pericardium are the same; namely, the extensive dulness on percussion and the undulatory impulse.

Causes, Prognosis, and Treatment of Pericarditis.

Causes of Pericarditis.—The most frequent causes are blows or excessive pressure on the præcordial region, inflammation propagated from the lungs or pleura, and, far above all, rheumatism. From this cause, children and young persons suffer much oftener than others. The remaining causes are those of inflammation in general, viz. cold, febrile excitement, &c.

[The disease may affect the fœtus in utero. In children that have died in less than forty-eight hours after birth, adhesions have been found between the pericardium and heart so strong as to lead to the belief that the disease had existed for some time prior to birth.]

Prognosis.—This disease, supposed by Corvisart to be necessarily fatal, has, by subsequent experience, been proved curable,—and completely curable; but as the possibility of effecting a complete cure is limited to a very brief period, and as, unless it be complete, the patient almost inevitably dies sooner or later from the consequences, the disease must be regarded as one of the most formidable incident to the human race. Some of these consequences we shall describe in the next section under the head of *adhesion of the pericardium*.

Treatment of acute Pericarditis.—The antiphlogistic treatment, in as energetic a form as circumstances will allow, should be employed with the utmost promptitude. The loss of a few hours at first may be irretrievable; and hence hesitation and indecision may seal the fate of the patient. If the attack be recent, and the patient's strength will admit, blood should in the first place be drawn freely and by a large incision from the arm, so as to bring him to the verge of syncope. From five-and-twenty to forty leeches, according to the strength, should then be applied to the præcordial region, so soon as the faintness from the venesection disappears, and reaction commences, which generally happens in the course of from ten minutes to an hour or two. Unless the pain be completely subdued by these measures, the leeching may be repeated two, three, or more times, according to the strength, at intervals of from eight to twelve hours; or, what is a better rule, so soon as the pulse and action of the heart denote a recommencement of reaction.

It is not, however, in every case that so active a treatment is required: we have seen a single prompt and abundant application of leeches, or a cupping, at once subduc every formidable symptom. When the patient, either from age, a feeble constitution, or the advanced state of the malady, cannot bear extensive depletion, local bleeding is, according to our observation, decidedly preferable to general; but it should be practised effectually, by cupping to twenty ounces or more, or by the application of from twenty-five to thirty or forty leeches. When, from depletion having already been carried to a great extent, or from the advanced stage of the disease, it is not safe to draw much more blood, yet it appears expedient from the persistence of pain, &c. to draw some, we have generally found that a smaller quantity drawn by cupping, produced more effect than a larger by leeching. The cause of this probably is, that by cupping it is drawn more expeditiously.

[Of late years it has been strenuously advised to bleed largely and repeatedly; and M. Bouillaud (*Nouvelles Recherches sur le Rheumatisme articulaire aigu en général*, &c. &c., 2d edit. Paris, 1830,) asserts, that he has, by this plan, rarely failed to cut short the disease, when he has been called early. He generally bleeds three or four times from the arm, to the amount of sixteen ounces each time, within the first three or four days, and employs leeching and cupping very freely. It is certainly good treatment to endeavour "to strangle" the inflammation at the onset by bloodletting; but if it should not succeed, when aided by the agents mentioned below, no time should be lost in having recourse to mercurial and other revellents. The safest course—even should the pulse be irregular and feeble, and the signs of general debility considerable—is to bleed, if the disease has been of short duration; but, on the other hand, as the writer has remarked elsewhere, (*Practice of Medicine*, 2d edit. i. 466,) the cupped and buffy appearance of the blood must not induce the practitioner to push the lancet too freely; for this, especially where the disease has a rheumatic origin, will commonly continue in spite of the bloodletting; and, it is affirmed, will even augment under its use.]

While the bleeding is in progress, other means should not be neglected. The intestinal canal, if at all confined, should immediately be evacuated by a purgative enema. Three drachms of senna leaves, and an ounce of sulphate of soda infused in a pint of boiling water and strained, answers the purpose. At the same time, five grains of calomel with five or ten of comp. extr. of colocynth, and two or three of extr. of hyoscyamus, should be given, and in two hours be followed by a senna draught.

The strength of the remedies employed must in each case be apportioned to the vigour of the patient's constitution; but the object is the same in all—expeditiously to prostrate the action of the heart, and for a time to keep it prostrate by preventing the re-establishment of reaction. If this object can be accomplished for the first twenty, thirty, or forty hours, the disease frequently does not rally, but remains perfectly under the control of remedies. We feel satisfied that a degree of activity in the first instance, which to some may appear excessive, is an ultimate source of economy to the strength of the patient; for the disease is subdued at once, and the protracted continuance of depletory measures, the most exhausting to the constitution, is rendered unnecessary.

In addition to the above measures, diluent cooling drinks, as four scruples of supertartrate, or two of nitrate of potass in a quart of water, and flavoured at pleasure, should be allowed in unlimited quantity, in order, by diluting the blood

there is inflammatory constriction of the orifices, a murmur will attend both sounds. Should the heart be dilated, as is frequently the case, the sounds will be increased; and should hypertrophy be conjoined with the dilatation, the impulse will sustain a corresponding augmentation of force

to render it less stimulant to the heart. Nauseating doses of tartrate of antimony, as one-sixth to one-eighth of a grain, every two hours, may be employed with advantage. [Or it may be given in contra-stimulant doses from 12 to 24 grains in the day, in divided doses, where the necessary tolerance exists. Colchicum often proves useful, and it has often been thought especially so when the disease is of rheumatic origin.] The diet should consist wholly of the weakest slops, as barley-water, gruel, weak tea, arrow-root, &c.

But the antiphlogistic treatment alone is not to be relied upon: rarely, if ever, does it, in a severe case, effect a complete cure. The practitioner sees all his resources gradually exhausted, while the disease proceeds with an even, uncontrolled tenor to its fatal termination. Sometimes, indeed, all the other symptoms disappear, but the action of the heart remains stronger than natural; at other times the heart even regains its healthy action, and the cure appears complete: yet in both these cases the palpitation, accompanied with symptoms of organic disease of the heart, recurs when the patient resumes his accustomed occupations. The reason of this is very intelligible. Unless the effused lymph, as well as the serum, be absorbed, it causes an adhesion of the pericardium, and thus establishes destructive disease. Now antiphlogistic measures can neither prevent the effusion of lymph, nor with any degree of certainty cause its absorption. Mercury *can* do this, as is visibly displayed in iritis; mercury, therefore, is the sheet-anchor of the practitioner. Dr. Latham is of opinion that its success is restricted to the condition of its producing salivation rapidly. From many observations we are satisfied of the general truth of this remark, and would therefore give the remedy on this principle; but we have seen cases in which cures, not falsified after many months, were effected, though salivation was not produced. The mineral, however, was freely administered, and probably produced its specific effect, though not in an apparent manner. From five to eight grains of calomel, or from ten to fifteen of blue pill, prevented from purging by a grain or a grain and a half of opium, three times a day, commencing after the first bleeding and a purgative, generally produce the effect with sufficient expedition. Inunction may be superadded or partially substituted, if mercury, taken internally, disagree. A manifest abatement of the symptoms generally takes place immediately on the effect of the remedy becoming apparent in the mouth, especially if a free salivation is established within the first thirty or forty hours. It should be maintained for a week or ten days, or even longer, unless the symptoms completely yield before the expiration of this period.

Should pain continue in the advanced stages of the malady, and after the period for applying leeches has passed, blisters may be resorted to, and repeated in quick succession, with great advantage. I have occasionally found a third or a fourth necessary before the pain has been completely removed. In the repetition of blisters, as well as of leeches, cupping, and venesection; and in the selection of one of these remedies in preference to another, much must necessarily be left to the judgment of the practitioner. It is only experience which can teach the exact adaptation of remedies to the circumstances. It must also be left to his discretion whether to give sedatives or not. When the restlessness and nervous irritability were great, we have seen much benefit derived from tinct. hyoscyami, *m*xv. ad xx. with the same quantity of tinct. digitalis, in a draught three or four times a day. Sedative remedies, however, should not be given until the first severity of the inflammation has subsided; nor should they ever be allowed, by producing their poisonous effects, to confuse the symptoms, already sufficiently complex, in the latter stages.

During convalescence it is sufficient to say that a very sparc unstimulating diet and extreme tranquillity must be imperatively enjoined, until the action of the heart has become perfectly and *permanently* natural.

An individual who has recently been affected with pericarditis is peculiarly liable to a recurrence of it, especially if it has resulted from rheumatism, and if the reparation has been incomplete. In this case, should rheumatism return, it rarely fails to be accompanied with a renovation of the pericarditic symptoms.

This cannot be a subject of surprise; for it is consistent with general analogy that a part recently injured by inflammation is more susceptible than a healthy tissue of inflammatory action; the reason of which probably is, that the vessels of newly organized adventitious structures are more tender and irritable than others. Secondary inflammation, however, has not the same energy and intensity as that of a healthy structure; it yields more promptly to curative measures, and is more completely within the powers of medicine. Hence a first attack of pericarditis is more dangerous than any subsequent one. It is comparatively rare for a patient to die from the direct effect of a recurrent attack; and, what is still more remarkable, he may sustain several without being left in a materially worse condition than after the first.

Much discretion, however, is requisite on the part of the practitioner to bring such recurrent attacks to a favourable termination; and the danger of doing too much is, perhaps, greater than that of doing too little. He must, in particular, be cautious of bleeding too extensively, with the object of reducing the excessive energy of the heart's action; for this energy, he must recollect, is a consequence not of the inflammation only, but partly also of an organic affection of the organ left by the primary attack. Nor is there the same motive for a vigorous employment of mercury; for the heart being already irreparably disorganized, it would be chimerical to entertain the expectation of effecting a *perfect* cure. The object, therefore, should be simply to prevent deterioration by combating the inflammation as it presents itself.

For the accomplishment of this object, a moderate use of bloodletting and mercury suffices; and leeching or cupping on the præcordial region is more efficacious and less exhausting than venesection. Blisters are, in these cases, peculiarly beneficial; and they may be repeated in quick succession as often as they are required and can be borne. When there still remains a little lingering pain, which scarcely authorises vigorous

measures, but cannot prudently be left, the most valuable and convenient remedy has appeared to us to be, a plaster composed of a scruple of tartrate of antimony, five scruples of the emplast. picis comp. and one scruple of wax to diminish the tenacity of the adhesion.

In these cases, also, where the sufferings of the patient, though perhaps not severe, are very protracted, and accompanied with much loss of rest, great advantage is derived from a pill of from three to six grains of extr. of hyoscyamus at bedtime, and moderate doses of tincture of digitalis during the day, the specific poisonous effect of the latter remedy being obviated by omitting it for a couple of days after every three or four.

Treatment of Chronic Pericarditis. — When pericarditis is essentially chronic, and the cavity appears to contain fluid, counter-irritant remedies are the most suitable. After what has already been said, it will be sufficient merely to mention blisters, either in succession or kept open with savine cerate, the tartrate of antimony and pitch plaster, and likewise issues and setons. The last remedy, however, generally creates so much irritation as to do more injury by deteriorating the general health, than good by its local effect. Mercury to a moderate extent may, if discreetly employed, be advantageous by promoting absorption; but in general the patient is too much reduced by constitutional irritation to admit of more than the mildest action of this remedy.

The diet may in chronic cases be more nutritious, comprising light animal food and broths.

II. Carditis.—Inflammation of the muscular substance of the heart may be, 1. universal, 2. partial.

1. Of universal carditis, with effusion of pus generally throughout the muscular tissue, there is not to our knowledge more than a single instance on record, and that occurred to Dr. Latham. "The whole heart," says he, "was deeply tinged with dark-coloured blood, and its substance softened; and here and there upon the section of both ventricles, innumerable small points of pus oozed from among the muscular fibres. This was the result of a most rapid and acute inflammation, in which death took place after an illness of only two days." (Lond. Med. Gaz., vol. iii. p. 118.) Laennec, never having met with or heard of a case of this kind, and considering an effusion of pus the only unquestionable sign of carditis, says, "there does not perhaps exist a single incontestable and well-described example of *general* inflammation of the heart, either acute or chronic." (De l'Auscult. t. ii. p. 554.) Independent of the above instance, however, there are probably many others, which, though not attended with effusion of pus, will come under the denomination of universal carditis; for few will concur with this distinguished writer in excluding from the proofs of carditis softening and induration, with increased or diminished colour of the organ. These are results of inflammation in other muscles, and analogy points out that they have the same origin in the heart. Further evidence is derived from the fact that, in cases of pericarditis, the characters in question sometimes occupy only a certain depth of the exterior surface of the organ, whence the presumption is almost positive that they originate in an extension of the inflammation from the pericardium. The cases of this description that are on record, are too numerous to be quoted. Several have fallen under our own observation. In this point of view, then, general carditis is not very rare.

As softening and induration are of sufficient importance to demand separate articles, we refer the reader to them for all that remains to be said on general carditis.

We have already stated, when treating of pericarditis, that this affection is greatly aggravated by the coexistence of carditis. As the treatment of the two is the same, it is unnecessary here to enlarge on it.

2. Partial carditis, characterized by the existence of an abscess or ulceration in the walls of the heart, is not very uncommon. Bonetus, in his Sepulchretum, has described a considerable number of cases. Abscesses are more rare than ulcers. The latter occur both on the external and the internal surface of the heart, and are consequent sometimes on inflammation of the membranes of those surfaces, and sometimes on steatomatous deposition in the cellular tissue beneath the lining membrane. The external ulcer is uncommon, but Olaüs Borrichus, Peyer, and Graetz have left perfect descriptions of it. The first says, "Cordis exterior caro, profundè exesa, in lacinias et villos carneos putrescentes abierat." The internal ulcer is more common. Bonetus, Morgagni and Senac present many cases. We have met with two or three.

An ulcer, whether external or internal, may perforate the heart.

The signs of abscesses and ulcers vary in different subjects, and are not distinguishable from those of other affections. "I know not," says Laennec, "if auscultation will afford any more sure signs, and I avow that I think not." (De l'Auscult. t. ii. p. 664.)

Ulceration is the most frequent cause of rupture of the heart,—fortunately a very rare occurrence.

The existence of gangrene of the heart has never been distinctly proved, and the following reasons lead to the belief that its occurrence is perhaps impossible: first, the muscular tissue is one of those least susceptible of it; and, secondly, inflammation of the heart sufficiently intense to occasion it, is fatal to the patient before gangrene can take place. The cases on record of reputed gangrene, appear to have been nothing more than softening, which incipient putrefaction had rendered more analogous to gangrene.

Adhesion of the Pericardium. — Pericarditis, both acute and chronic, and especially that originating in rheumatism, frequently terminates in adhesion of the pericardium. Lancisi, Vieussens, Meckel, Senac, and Corvisart, are of opinion that, with a complete and intimate adhesion, the patient cannot live in a state of health. We know not how it is that Laennec and Bertin have formed an opposite opinion. The former states that he had opened a great number of subjects so affected, who had never *complained* of any derangement in the circulation or respiration; whence he infers that adhesion often does not in any respect interfere with the exercise of those

functions. Our experience is entirely opposed to this doctrine. The *complaints* of the patient are, perhaps, not a just criterion, for we have often found the working classes disclaim dyspnœa when labouring under enormous hypertrophy and dilatation, and when that symptom obviously existed in a great degree. Many others, also, especially children, are naturally inattentive to their own sensations, and close interrogation is the only mode of ascertaining that after the attack of pericarditis they became incapable of some exercises, habits, or efforts, which they previously accomplished with facility.

We have never examined a case of complete adhesion of the pericardium without finding enlargement of the heart, — generally hypertrophy with dilatation. We have observed that cases of adhesion terminating in enlargement often hurry to their fatal conclusion with more rapidity than almost any other organic affection of the heart; and we have, on the other hand, repeatedly seen patients die from the consequences of an adhesion, the history of which we could trace back, eight, ten, or more years; yet such individuals would not unfrequently represent their health to have been perfect during the greater part of that period, and would not admit, until closely interrogated, that they had been more or less "short-winded." Hence we infer that, though adhesion may not for a time create much inconvenience, its effects are ultimately fatal. This refers, of course, to intimate, not to loose adhesion. It appears to us that a tranquil, abstemious life, by which in other forms of organic diseases of the heart existence may sometimes be prolonged to its natural period, cannot be equally availing here; for as the action of the organ itself is a constant struggle, repose is impossible.

How adhesion occasions hypertrophy is easily understood; for the organ must increase its contractile energy, in order to contend against the obstacle which the adhesion, by shackling its movements, presents to the due discharge of its function, and, as explained in the article Hypertrophy, increased action leads to increase of nutrition. The cause of the coexistent dilatation is not less manifest; as the shackled organ transmits its contents with difficulty, in a state of greater congestion than natural, and, as is more fully explained in the article on dilatation, permanent distension is the most effective cause of this affection. When the muscular substance is softened, as frequently happens, dilatation takes place much more readily, in consequence of the deficient elasticity or tone of the heart's parietes.

When adhesion of the pericardium has produced hypertrophy with dilatation, its history identifies itself with that of the latter maladies, of which it renders the symptoms more severe and the progress more rapid. To avoid repetition, therefore, we refer the reader to the article Hypertrophy, and shall, here, only describe the signs which are pathognomonic of adhesion.

These signs have generally been considered very obscure. Dr. Sanders believed that he had discovered one of a positive nature in a dimple or retraction taking place, as he states, during the ventricular systole, in the epigastrium immediately below the left false ribs. We have searched for this attentively in several cases of adhesion, but have not been able to detect it in any degree which could constitute a sign. Laennec, who was equally unsuccessful, thinks that it could not take place unless the stomach, by adhering both to the diaphragm and the abdominal parietes, formed the medium of retraction.

In five or six cases we have remarked one sign, which has not, to our knowledge, been hitherto noticed; namely, the heart, though enlarged, beats as high in the chest as natural, and sometimes occasions a prominence of the cartilages of the left præcordial ribs. We should, indeed, naturally expect that the adhesion would brace up the organ, and that, when enlarged and not able to descend, it must, being bounded behind by the spine, force the walls of the præcordial region forward.

Another sign, and perhaps the most characteristic of all, is an abrupt, jogging, or tumbling motion of the heart, very perceptible in the præcordial region with the cylinder. It is more distinct when the heart is hypertrophous and dilated; and under these circumstances we have found the jogs correspond with the ventricular systole and diastole respectively, that of the diastole being sometimes nearly as strong as the other, and having the character of a receding motion. This jogging motion is distinguished from the undulatory movement of fluid in the pericardium, both by its nature, by the synchronism of the jogs with the sounds, and by the feeling that the heart at each systole comes in immediate contact with the thoracic walls.

A third sign consists in a bellows-murmur with the first sound, which we have always found present when the heart is enlarged and acting vigorously. Nor is it, in every case, confined to the heart: we have often heard it in the aorta, and formerly experienced difficulty in discriminating it from the murmur of dilatation of this vessel. (Vide Treatise, by Dr. Hope, p. 63.) Although, when the heart is dilated, the murmur in question may be occasioned partly by the relative smallness of the orifices, and the greater angles at which the currents meet in them in consequence of the unusually rounded form of the ventricles, as elsewhere explained, it is also, we believe, occasioned in a great measure by the sudden velocity with which the fluid is propelled, as it would not otherwise exist in the aorta.

J. Hope.

PERICARDIUM, DROPSY OF. See Hydropericardium.

PERITONITIS, from *περιτόνειον*, *peritonæum* —This is the term now universally used to express an inflammatory state of the serous membrane which lines the interior of the abdominal cavity, and invests all the viscera contained therein.

Pain, tumefaction, and tenderness of the abdomen on pressure, are the most prominent symptoms which characterize this affection during life; and increased vascularity, thickening, effusions of coagulable lymph, of serum, of pus, or blood, are the principal local effects produced by it. These elementary features, accompanied in general with more or less of pyrexia, will exist in different de-

grees and combinations, in every variety of age, sex, or constitution, modified, however, by circumstances derived partly from the nature of the cause, and partly from the condition of the patient at the time of the attack.

Peritonitis may assume either the acute or chronic form. It may exist as a sporadic disease, or prevail as an epidemic. It may either present itself openly, with a numerous group of well-marked symptoms, or creep on in a latent state, with scarcely one of its characteristic features. It may be limited in its extent to a small portion of membrane, or spread over a large surface. It may run its course uncombined with any other affection, or be complicated with various diseases. There is no period of life exempt from its attacks. It may affect the infant, the adult, and the puerperal female: pursuing the same course, and exhibiting similar effects in all, it yet presents a vast variety of symptoms in individual cases, principally according to the organ whose peritoneal covering is the chief seat of the inflammation.

Pure peritonitis is exclusively confined to the peritoneum, without involving the muscular or mucous tissues of the intestines, and can in most cases be distinguished by peculiar symptoms from inflammatory affections of those tissues. Not uncommonly, however, inflammation commencing in one tissue extends to those contiguous; but this is by no means uniformly the case; frequently the very opposite effect is induced in this disease, and the intestinal mucous membrane becomes remarkably pale, while the peritoneum is acutely inflamed.

We shall proceed, in the first place, to notice the disease as it exists in the acute form in the different periods of life.

I. Acute Peritonitis in the Infant.—This disease may attack the infant during its intra-uterine life. Its exciting causes during this period of existence are obscure: they may possibly be transmitted from the mother to the infant, or originate from an internal strangulation of the intestines, of which M. Legoues and M. Ducis have seen examples. However difficult it may be to assign a satisfactory cause for its origin, its existence has been unequivocally demonstrated by the post-mortem appearances which infants who have died a few hours after birth have exhibited. In some cases of this kind, the usual effects of peritoneal inflammations, adhesions between the intestines, false membranes, and sero-purulent effusions into the abdomen, have been detected—effects which must have been produced during the abode of the infant in utero. Five cases of infants who died a few hours after birth have been detailed by M. Billard, in which the above appearances were found. In one instance the child was emaciated and pale; and old, solid adhesions were discovered in the abdomen, apparently indicating that the disease had existed for some time previous to birth, and had probably become chronic before it terminated fatally. In the other four cases, the infants presented nothing unusual in their external appearance.

The causes which may excite peritonitis during the period of lactation are not very evident. They probably are essentially the same as may operate during adult years. Infants are exposed, to a certain extent, to similar injurious impressions from external agents, and their organs are at least equally susceptible of morbid actions.

Symptoms.—The abdomen of the child presents a tumefied and tense appearance, and is elevated in a point towards the umbilicus. This distension is caused in the early period of the disease by flatus in the intestines: it is accompanied by some dyspnœa, which does not, however, always indicate a pulmonic affection, but is produced by the obstruction which the diaphragm suffers in its descent from the distended abdomen, and the pain which its movements occasion by the friction of the inflamed peritoneal surfaces against each other. There is constant abdominal pain, which is much aggravated by pressure. The countenance exhibits an expression of suffering: the features are contracted, and the little patient cries almost without intermission. Vomiting usually is present, and the bowels are in most cases constipated. There is restlessness, with general debility; hot, dry skin, and frequent, weak pulse; and, if prolonged into the chronic state, the child becomes emaciated, and dies exhausted.

It is difficult to distinguish this disease from infantile enteritis, with which it is occasionally complicated. In its simple form it is usually attended with more abdominal tenderness on pressure. Constipation generally exists in peritonitis, while diarrhœa is frequently an attendant on inflammation of the mucous membrane. The appearance of the tongue may assist in the diagnosis, being, in the latter affection, generally furred with red tip and edges, and red papillæ, while in simple peritonitis this redness is not generally present. Peritonitis is a much less frequent disease during infancy, not being so likely to be induced by irregularities of diet and the other injurious agents to which children are particularly exposed, and which are common exciting causes of enteritis. M. Billard observes that it may be distinguished from pleuritis by the sonorousness of the chest, and from flatulent colic by the pains being remitted in the latter affection, and ceasing on the expulsion of gas. (Maladies des Enfans, Paris, 1828, p. 449.) The prognosis in this disease is generally unfavourable. The post-mortem appearances do not differ from those which the disease presents in adults, and which will be hereafter described.

Children of a scrofulous habit are subject to a form of chronic peritonitis, which deserves distinct notice: it is characterized during life by great tenderness of the abdomen on pressure, with occasional paroxysms of acute pain, at first coming on only once or twice a day, but afterwards becoming more frequent, after which the child appears quite lively, and free from indisposition. At first the pain is limited, but afterwards extends over the whole abdomen, which in the early stages becomes swollen and tense, but afterwards subsides: the pulse is generally about 100, with some strength and fulness, the tongue clean, appetite irregular, but generally good, and frequently voracious; some thirst, the bowels free, the evacuations unusually large in quantity, and peculiar in appearance, consisting generally of a whitish-brown matter, of the consistence of a thin pudding. This state of the bowels may continue for six weeks or

two months with progressive emaciation, until diarrhœa, attended with petechiæ, puts a period to the child's life. The head seldom suffers, but cough and dyspnœa occasionally attend. The usual duration of the disease is four or five months, but often the child is not confined to his bed till the last month. Dissection exhibits the mesentery, bowels, and peritoneum lining the parietes, united together into one mass; the peritoneum thickened, and containing large masses of scrofulous matter; the intestinal mucous membrane perforated by ulcerations, which form numerous communications between the different coils of intestine; and the intestines and abdominal cavity containing matter resembling that which was passed during life by stone. The causes of this disease are unknown, and it in general terminates fatally. Dr. Gregory recommends leeches and fomentations during the early stages, afterwards purgatives, mercurial alteratives, tonics, chalybeates, and absorbents. Laudanum affords the only relief from the pain. This disease appears to be a frequent cause of infantile marasmus. (Medico-Chirurg. Trans. vol. xi. p. 262. Dr. Gregory on Scrofulous Inflammation of the Peritoneum.)

II. *Acute Peritonitis in the Adult.*—The causes which predispose to peritonitis in mature years are involved in some obscurity. They probably do not differ essentially from those which predispose to other inflammations. It is observed to be more common during adult years than at other periods of life; in women than in men; and in sanguine and plethoric individuals than in the opposite constitutions. A disposition to local determinations of blood, proved by previous inflammatory attacks and repeated discharges of fluids, is, according to Broussais, a common predisposing cause, and to this may be added cold seasons of the year, residence in damp situations, the abuse of intoxicating liquors, and over-excitement of the passions.

The exciting causes may be arranged in three classes—the *mechanical*, the *chemical*, and the *vital*.

The *mechanical* causes include all injuries inflicted on the abdomen by blows, falls, or compression, pressure of the gravid uterus, extra-uterine conceptions, enlarged ovaries, or other morbid growths within the abdomen. Under this class may also be included all wounds of the peritoneum, whether the result of accident, surgical operations, or strangulation arising from hernial protrusions, or invagination of a portion of intestine. M. Broussais considers violent and long-continued corporeal exertions, violent and repeated contractions of the abdominal muscles in vomiting, strictures of the colon or rectum producing unnatural contortion, and friction of the intestines on one another, as causes of peritoneal inflammation.

The *chemical* causes include all extravasations into the peritoneal cavity not quickly absorbed, whether of blood, urine, bile, chyle, or fæces, and perhaps the morbid serous secretions of the membrane itself.

The *vital* causes comprehend all aberrations of healthy actions, transmission of morbid action from a part previously affected to the peritoneum, or extension of inflammation from a contiguous organ or tissue to this membrane.

An aberration of action takes place when certain functions of the system are interrupted, as when the perspiration, the catamenia, or the lochia are suppressed, and peritonitis is induced as a consequence. The remote cause in these cases arises from the operation of cold, moisture, or both combined, applied to the surface, or the drinking of cold liquids when the body is over-heated. Transmission of morbid action or metastasis may be ranked among the exciting causes. We see examples of this when the retrocession of rheumatic, arthritic, erysipelatous, or other inflammations, is quickly followed by an inflammation of this membrane. According to M. Broussais, the chill of an intermittent, when the abdominal viscera, and especially the spleen, are suddenly swelled by the centripetal motions of the fluids, may prove an exciting cause of peritonitis, examples of which he has frequently seen during the course of these diseases.

Extension of inflammation from a contiguous texture or organ to the peritoneum, is a very frequent cause of this affection. Thus, when the gastro-intestinal mucous membrane is inflamed, the inflammation may extend itself to the serous envelope of the intestines; or when the uterus or any other of the abdominal viscera are similarly affected, the inflammatory action may be propagated to their peritoneal coverings, and the two diseases may either coexist, or a revulsion of the phlogosis takes place, the primary affection subsides, and simple peritonitis is established. This subject, however, will be more fully considered when we come to treat of the complications of this disease.

Symptoms of Acute Peritonitis.—This affection frequently commences by a shivering more or less prolonged, accompanied by a feeling of general indisposition and weariness in the limbs: at an uncertain period, reaction takes place, and heat of skin more or less pungent, with headach, constriction at the epigastric region, and frequent, hard, concentrated pulse, succeed, attended with a sensation of heat and pain in the abdomen, and tenderness on pressure. This pain soon becomes the principal symptom of the disease, and is not unfrequently the first which appears, not being preceded by any general febrile symptoms: it is usually of an acute, tensive, pungent character, and has been compared by some patients to the sensation which a cutting instrument or a screw introduced into the affected parts would produce. It varies much in its permanency, seat, and degree: in some cases the pain comes on in paroxysms, which continue for a short time, and then pass off, leaving in the intervals only an acute tenderness. "These accessions," says Abercrombie, "seem to be excited chiefly by flatus moving through the bowels and distending the inflamed part, and the action of a purgative is often followed by a violent aggravation of all the symptoms." (Abercrombie on Diseases of the Stomach, &c. p. 151.) In other instances the pain is permanent, and is confined to a single spot of small extent, in which it continues to preserve its intensity during the whole course of the disease: in other cases, again, the pain shifts from one part of the abdomen to another, and sometimes extends nearly over the whole membrane. The pain differs much in its degree, and may even sometimes be altogether absent, or

only felt on pressure: in other instances it is very severe, and much increased by the erect posture, or any motion of the body; hence the patient lies constantly on the back, and cannot, without an increase of suffering, lean to either side, finding most relief from remaining motionless, with the knees in a slight degree elevated. This position, while it throws the weight of the intestines on the spine, and therefore removes pressure from the inflamed membrane, at the same time relaxes the abdominal muscles, and prevents any stricture on the anterior surface of the inflamed parts. The respiration is frequent, small, and interrupted, and chiefly performed by the thoracic muscles, the depression of the diaphragm producing on the affected parts the same effect that pressure does on the abdomen; consequently, full inspiration, coughing, sneezing, vomiting, or the evacuation of the urine or fæces, aggravate the pain.

The increased sensibility of the abdomen is sometimes not perceived unless when pressure is made; but in other cases the soreness is so exquisite, that the slightest weight on the abdominal parietes aggravates it to an intolerable degree. The pressure of the bed coverings becomes insupportable, so that it is found necessary to keep them from being in contact with the abdomen by artificial means. This sensibility to pressure is the grand criterion by which we are to judge of the existence and degree of the disease; "and this," it has been observed, "we are not to estimate solely by the complaint, but by the countenance also of the patient. Even gentle pressure causes a sudden retraction of the lips and expression of pain, as if he were pierced by a sharp instrument. On the other hand, we are not to overrate the tenderness (though it is the surest diagnostic) by the wincing of the patient, especially if very irritable or young, or afraid of being hurt, or if the bowels happen to be uneasy and distended with flatus at the time."*

In addition to pain and tenderness on pressure, tension and tumefaction of the abdomen are constant and characteristic symptoms of peritonitis: those in the early stages arise from a tympanitic distension of the intestines, though at a later period of the affection they may be caused by effusion of fluid into the peritoneal cavity. This swelling, which is equal and regular in general peritonitis, exists in different degrees in different individuals, depending partly on the intensity of the inflammation, and partly on the degree of resistance which is offered by the abdominal parietes. It is considerable with those whose belly is naturally flabby, or when the abdomen has been recently distended, as in females after parturition, and in both sexes after the operation of paracentesis. In individuals, on the contrary, with strong abdominal muscles, and particularly in thin robust men, the abdomen is scarcely at all swelled; sometimes it is evidently retracted, especially in the first days of the attack; in such cases it is very hard, and in general the hardness and tumefaction are in the inverse ratio of each other. (*Chomel*, Dict. de Médecine.)

Along with these symptoms there are frequently present, singultus, nausea, and vomiting, the matter ejected being at first the contents of the stomach at the time of the attack, afterwards mucus or bile. The bowels are in general obstinately costive, though occasionally relaxed. The pulse, as the disease advances, is in general very frequent, ranging from 120 to 130 in the minute; it is also very small, as if not only the heart but the artery at the wrist had contracted upon itself; yet if it be accurately examined, it will be found, during the stage of excitement, firmer than natural, almost feeling like a small whip-cord or harp-string. The tongue is covered with a whitish fur, the urine is scanty and high-coloured, and there is excessive thirst, which the patient fears to gratify, in consequence of the vomiting which the introduction of fluids into the stomach often induces. (*Armstrong*, Morbid Anatomy of the Bowels, p. 92.)

The course of acute peritonitis is in general rapid, and marked by a progressive increase of all the above symptoms: the abdominal pain, tenderness, and tumefaction become aggravated, the face more pale, the features contracted, and often covered with a cold sweat,† the pulse more frequent, and anxiety augmented. The malady may remain stationary for some days with nocturnal paroxysms, either marked by a febrile exacerbation or an aggravation of the local symptoms, and may not terminate fatally till after thirty or forty days; but in most instances it runs a much more rapid course, and in some cases the patient sinks in sixteen to twenty-four hours from the commencement of the attack.

The approach of death is marked by cessation of the pain, by the pulse becoming quicker, smaller, and very weak, feeling like a soft undulating line; by coldness of the extremities, and ultimately of the entire surface of the body. The abdomen becomes more tumid and tense, but in some instances soft and relaxed; the face is sunk, and especially hollow round the orbits; the vomiting is succeeded by regurgitation of the liquid contents of the stomach without any apparent effort; and although the intellectual faculties are often preserved unimpaired to the last moment, sometimes delirium, a comatose state, or in other instances convulsive movements of the head or limbs, precede the fatal termination.

* *Dr. Dickson:* see Lond. Med. Chirurg. Rev. Sept. 1820. In order to form an accurate idea of the sensibility of the abdomen, the hand should be laid flat on its centre, and then passed successively on every part of it, the physician observing at the same time the patient's countenance, which will at once indicate pain if the abdomen be sensible. Care should be taken not to make pressure with the ends of the fingers; for then, by being applied to one point, it becomes considerable, and will excite pain where there may be no disease. (Martinet's Pathology, translated by Quain, third edit. p. 68.)

In some subjects the thickness of the muscles and parietes of the abdomen renders the pain on pressure scarce perceptible. In such cases M. Broussais directs us to make lateral pressure towards the centre of the abdomen. "Elle (douleur) était plus difficile à supporter quand on la faisait (pression) latéralement en la dirigeant vers le centre. Ce signe est un des meilleurs pour faire découvrir les péritonites obscures." (Histoire des Phlegmasies, vol. ii. p. 492.)

† The French pathologists have given a peculiar term to the expression of the countenance in this disease, "face grippée." Slight contractions of the muscles of the face, and principally of the forehead, are caused by the force of the abdominal pains, by which the features are discomposed and appear drawn up towards the forehead, which is wrinkled and the nose pointed. (See *M. Gasc.* Dict. des Sciences Médicales, article Péritonite. *Roche et Sanson*, Elémens de Pathologie, tom. i. p. 585.)

Such is the assemblage of symptoms which acute peritonitis, in its simple and open form, presents: they are not, of course, all present in every individual case, but the greater number of them will be generally found to cocxist in well-marked instances of the disease. Cases, however, occasionally occur, in which nearly all the above symptoms are absent. This variety of the affection will be considered under a distinct head.

Acute peritonitis may terminate by resolution; by effusion; by gangrene; or it may assume the chronic form.

Resolution may take place between the fifth and twentieth day. It is indicated by a cessation of pain, fever, and other inflammatory symptoms, a re-establishment of the functions of the neighbouring organs, the capability of turning on the side, and of bearing pressure on the abdomen, disappearance of the nausea and vomiting, and sometimes by the appearance of a critical evacuation, such as diarrhœa, abundant urine, and copious perspiration; by the pulse becoming slow and soft, and by the return of quiet and refreshing sleep.

Effusion is a frequent termination in fatal cases. The fluid effused may be serum, pus, or in some rare instances blood. These fluids may either exist singly or in combination with each other, or with coagulable lymph. The symptoms which denote effusion are diminution of the abdominal pain, with sense of weight and oppression in the affected part, irregular chills, softness of the pulse, paleness of the countenance, and coldness of the extremities. (*M. Gasc*, Dict. des Sciences Médicales.) Effusion may be ascertained to exist in many instances by percussion, which, when made on the abdomen in the early stages of peritonitis, generally elicits a sonorous sound derived from the tympanitic state of the intestines; but, as the effusion increases, this sound becomes progressively more limited and obscure. Fluctuation can also occasionally be felt,* but in general only after the disease has existed some time; for, as Andral observes, during the early periods of the disease, the abdominal effusion, small in quantity, is rather to be discovered by the tension, resistance, and modification of form of the belly, than by the great increase of its volume or the existence of fluctuation. (Clinique Médicale, Maladies de l'Abdomen, p. 539.) Fluctuation may also be absent, if the effused fluid is contained in a number of distinct abscesses, separated from each other by partitions of false membrane, of which the same pathologist relates an instance. (Ibid. p. 598.)

It is doubtful, when pus and lymph are effused in any great quantity, if they are ever absorbed, and such cases generally terminate fatally, or pass into the chronic form of the disease. However, M. Gasc asserts that he has known patients recover in whom the purulent matter escaped by the umbilicus, (Dict. des Sciences Médicales, p. 508); and we have seen cases of ascites consequent on peritonitis cured by the aid of medicine.

[Auscultation may afford evidences of peritonitis before and after effusion has taken place. As in the inflammations of serous membranes, the first effect is to arrest the secretions, so that the membranes are dry; and careful auscultation has detected a sound of *frottement* or friction. (Barth et Roger, *Traité d'Auscultation*, Paris, 1841.) The effusion of coagulable lymph may be detected by like signs, as well as by the hand applied over the abdomen. In a case of peritonitis supervening on ovarian dropsy, described by Dr. Beatty, when the hand was applied over the umbilicus and its neighbourhood, the sensation communicated to it, when a full inspiration was taken, was that of a grating or rubbing together of two uneven and rather dry surfaces. By the aid of the stethoscope, a loud and distinct friction sound was audible over a space about five inches in diameter, with the umbilicus for a centre. Another pathologist, Dr. Bright, states that he has observed, on several occasions, that when the circumstances of the disease had rendered it probable that adhesion had taken place between the viscera and the peritoneum of the abdomen, a very peculiar sensation was communicated to the touch, varying between the crepitation produced by emphysema, and the sensation derived from bending new leather in the hand. It has been presumed by Dr. Corrigan that for the production of this sign, the effused lymph must be in an unorganized condition; and also by Dr. Beatty, that it is observed only in cases where one at least of the opposed surfaces is adherent to a solid resisting body; and it would appear from Dr. Stokes, that in twelve collected cases, nine presented an organic tumour.]

Gangrene is a much rarer termination; but M. Gasc observes that, of all serous inflammations, peritonitis, when intense, is most disposed to pass into a state of gangrene. The symptoms indicative of this termination are, sudden cessation of the abdominal pain, smallness of the pulse, which becomes concentrated and intermitting, extreme prostration of strength, Hippocratic countenance, and speedy death. Dr. Abercrombie considers this termination rare, and that it is not often found in *post-mortem* examination as a prominent appearance, but when met with is slight and partial, and always accompanied with extensive deposition of false membrane. It more frequently occurs when enteritis coexists with inflammation of the peritoneum.

When acute peritonitis does not prove fatal in the course of fifteen or twenty days, it generally subsides into the chronic form. It sometimes, however, continues acute for a much longer period, and has even been protracted, as already mentioned, to thirty or forty days, and proved fatal at the end of that period. The symptoms which indicate this form of the disease will be considered in a separate section.

Diagnosis.—This is frequently attended with considerable difficulty, as the inflammatory affections of the viscera and other parts which the peritoneum covers frequently present nearly similar symptoms as inflammation of this membrane. Neuralgia and rheumatic pains of the adjacent muscles and nerves may also occasionally be mistaken for peritonitis; and colic, the passage of calculi along the biliary ducts or ureters, have been considered by some writers as liable to be confounded with inflammation of the peritoneum.

* For the mode of examining the abdomen, see article Abdomen, Exploration of.

In gastritis the pain and tenderness on pressure are confined to the region of the stomach; the vomiting in general is more urgent, and is more easily excited by food or drink, and the thirst, with desire of cold liquids, is more intense. The state of the tongue varies in gastritis; but when it does present the thick coat on the centre, and intense redness of tip and edges, it will assist us in the diagnosis, as this appearance is not observed in simple peritonitis. When the peritoneal coat of the stomach is inflamed, the diagnosis will be more difficult, and can only be established by an attentive consideration of the general history and characters of the two diseases which have been already detailed.—See Gastritis.

We have frequent occasion to discriminate between enteritis and peritonitis in practice, and the symptoms are often so very similar that some physicians have thought a diagnosis between them impracticable. Dr. Cullen, after having given peritonitis a distinct place in his nosology, tells us, in his First Lines, that it is difficult to say by what symptoms it may be known, and that when known it does not require any remedies beside those of inflammation in general, and gives this as a reason for passing it over without further description. Dr. Philip Wilson, in his work on Febrile Diseases, asserts, "that peritonitis seldom exists without the inflammation spreading in a greater or less degree to the stomach and intestines, nor does inflammation of the latter frequently exist without extending to the peritoneum. There is hardly room, therefore, for regarding peritonitis as a distinct complaint." Nevertheless, the two diseases are essentially different, as well in the texture affected as in several of their symptoms, and in the *post-mortem* appearances which they present; and they can in many, perhaps in most, instances be discriminated. The treatment of peritonitis ought also, in some degree, to vary from that of enteritis.

John Hunter was fully aware of the distinct nature of these two affections, for he observes, "If the peritoneum which lines the cavity of the abdomen inflames, its inflammation does not affect the parietes of the abdomen; or if the peritoneum covering any of the viscera is inflamed, it does not affect the viscera. Thus the peritoneum shall be universally inflamed, as in the puerperal fever, yet the parietes of the abdomen and the proper coats of the intestines shall not be affected; on the other hand, if the parietes of the abdomen or the proper coats of the intestines are inflamed, the peritoneum shall not be affected." (On the Blood &c. p. 244.)

The most important diagnostic symptom between peritonitis and enteritis is the sensibility of the abdomen to pressure; in the former, pain is excited by a very slight degree of pressure, which would produce little or no inconvenience in the latter. The action of the diaphragm in full inspiration or coughing does not produce so much suffering in enteritis, nor is it so much aggravated by motion of the body or abdominal muscles. The pain appears much more superficial in peritonitis, and in many instances is not accompanied with sickness or any other disturbance of the intestinal canal. The pain in peritonitis in general is of a more acute character, and is more frequently accompanied with constipation. Enteritis presents some peculiarities according as it affects different portions of intestine, and the presence or absence of which will assist our diagnosis; these have been already fully considered. (See Enteritis.) When the duodenum is inflamed, pain in the situation of that viscus, and occasionally jaundice, are present. In inflammation of the large intestines, there are generally diarrhœa or symptoms of dysentery, neither of which affections are common in simple peritonitis; but when the jejunum or ileum is inflamed, it is more difficult to discriminate; the pain in such cases is in general not so severe as in peritonitis, and is principally in the regions which those intestines occupy.

Rheumatism sometimes, though rarely, affects the abdominal muscles, and may be mistaken for peritonitis, as it presents the same pain on pressure or motion; but the pain in such cases is principally felt at the origin or insertion of the muscles, shooting to the false ribs and the spine of the ileum. (See Parr's Medical Dictionary, vol. ii. p. 21.) In such cases the skin may be greatly distended, and if the muscles are swelled, the figure of each is often preserved. The existence of these peculiar symptoms, conjoined with the absence of uniform tumefaction, vomiting, or constipation, will probably in most cases enable us to form a correct diagnosis. Neuralgic pains of the abdominal viscera or parietes may simulate peritonitis. Andral observes (Clinique Médicale, tom. iv. p. 539,) that rheumatic patients are sometimes attacked with severe acute pains in the abdomen, which vanish more or less suddenly without leaving any trace of a severe affection; and M. Chomel states that in several cases acute pains suddenly occur in the abdomen, often without any appreciable cause, and last for ten or twelve hours, with frequent pulse, nausea, and vomiting, and yield to the use of opium. (Dict. de Médecine, tom. xvi. p. 330.) There is some reason to suspect that these pains may in certain cases originate from irritation of some portion of the spinal cord, or of the ganglionic nerves that are distributed to the different viscera.* Their fugitive characters, the absence of pyrexia or tumefaction, and the general history of the case, may enable us to ascertain their real nature. In doubtful cases we should examine attentively the spinal column, and if any tenderness or pain is evident in a particular spot, it will give an additional probability to our suspicions.

Hysteria frequently simulates peritonitis, and nothing but a careful consideration of the history of the case and watching closely its progress, can enable us to discriminate between them. In hysteric cases, as Dr. Bright well observes, in general some great incongruity of symptoms will be detected: a tenderness of the abdomen, indicating inflammatory action beyond any thing which the pulse or the condition of the tongue would authorize us to infer; a hurry and even labour of respiration, more marked than in the embarrassed breathing of peritoneal inflammation; a sudden subsidence of the symptoms, and their sudden

* See *Whatton*, On Spinal Irritation, North of England Med. and Surg. Journal, *Dr. Corrigan*, Lancet, and Lond. Med. Chir. Review, July 1831, p. 182. *Teale*, on Neuralgic Diseases.

return; a shifting and changing of the tender or painful part, and sometimes the decided intervention of hysteric symptoms, and the very frequent accompaniment of some evidence of mental causes, or of irritation and deranged function in the uterus itself,—all these, together with the general aspect of the individual, will frequently be guides and indications to assist us. (Bright's Reports of Medical Cases, p. 453.)

Colic may be distinguished from peritonitis by the absence of fever, the pain being relieved by pressure, the state of the pulse, and the suddenness of the attack. (See Colic.) There are several other affections which occasionally may present some of the symptoms of peritonitis which would lead us into too long a detail to consider. We have endeavoured to select those only which either occur most frequently or present the greatest difficulty in diagnosis. Inflammation of any of the abdominal viscera, or the passage of calculi through the biliary ducts or ureters, may occasionally resemble peritonitis, though they in general possess sufficiently distinctive characters. (See the different articles that treat of these affections.)

Prognosis. — Peritonitis is always attended with considerable danger, but if subjected to active treatment at an early period there is a fair chance of effecting a cure, especially if the patient is not advanced in years, is of a good unimpaired constitution, and capable of bearing depletion to a considerable degree; or if the inflammation be limited in its extent and uncomplicated in its form, and the symptoms much mitigated by the evacuations employed. A favourable termination is indicated by the gradual diminution of abdominal pain, tension, and tenderness, the pulse becoming fuller, softer, and less frequent; the skin less parched, soft, and moist; the respiration less laborious, and the countenance more open and expressive of ease. An unfavourable result is to be expected when the patient is of advanced age, and of a debilitated or broken down constitution; when the disease originates from perforation of the stomach or intestines, or rupture of any of the abdominal viscera, or when it succeeds to a wound, a surgical operation, or to parturition; or extends over a large portion of peritoneal surface, or is complicated with an affection of any important organ. The danger is also greater when the inflammation has existed some time before the employment of remedies, and when the symptoms exhibit considerable intensity, and do not yield to the depletions employed.

Complications.—The fever which accompanies peritonitis may present either an inflammatory, typhoid, or gastric character. The former is met with most frequently in robust and vigorous patients; typhoid symptoms for the most part prevail in old persons of debilitated constitutions; and gastric fever will coexist when the gastro-intestinal mucous membrane is in a state of inflammatory excitement. The symptomatic fever may be so modified by the state of the patient at the time of the attack, by the coexistence of other morbid actions, and the prevailing epidemics of the season, as to present a variety of intermediate grades. In some instances peritonitis has been complicated with an intermittent fever, disappearing during the intervals, and re-appearing on the accession of each paroxysm. (*Andral*, Clinique Médicale, tom. iv. p. 571.) In some instances it has assumed a tertian or quartan type; (*Roche et Sanson*, Elémens de Pathologie, tom. i. p. 591); but such cases are rare. Andral relates an instance of peritonitis supervening on the disappearance of rheumatism; but it is most frequently complicated with affections of the abdominal viscera, especially of the stomach or intestines; the inflammation spreading from the peritoneum to the other contiguous tissues which form their parietes, or pursuing an opposite course, attacking primarily their mucous membrane, and afterwards penetrating to and affecting the peritoneum. It appears sometimes to coexist with an hepatic affection, and Chomel mentions a form of peritonitis called *bilious*, in which the peculiar symptoms of peritonitis were accompanied with a yellow coating of the tongue, discharges of bile from the stomach and intestines, with a yellowish tinge and pungent heat of skin. (Dict. de Médecine, loc. cit.) M. Broussais observes that the excess of pain is capable of disorganizing the brain by a too impetuous afflux of blood into its capillaries, and that after much suffering, the delirium, convulsions, and coma are frequently the effect of the disease of the brain itself. (History of Chronic Phlegmasiæ, translated by Hays and Griffith, vol. ii. p. 359.)

The lungs and pleura may also be affected simultaneously with the peritoneum, in which case thoracic pain, cough, dyspnœa, and other pectoral symptoms will be present. This complication is not very uncommon. M. Dugès found traces of inflammation of the pleura in forty cases out of two hundred and sixty subjects who died of puerperal peritonitis, and whose bodies he examined after death. (Journal Complémentaire, tom. xxxvi. p. 218.) The parenchyma of the lungs, or the pericardium may be also affected, but such cases are rare. Other complications may exist which would lead us into too long a detail to include: we trust sufficient has been said to impress on the mind of the medical practitioner the importance of directing his attention to the state of other organs and textures in cases of inflammation of the peritoneum.

[M. Chomel (*Dictionnaire de Médecine*, 2d edit. xxiii. 560, Paris, 1841,) is of opinion, from long observation, that spontaneous and primary peritonitis is a rare disease. In the space of fifteen years, he does not recollect a single case of fatal peritonitis, in which the assertion was negatived. In this respect, peritonitis is an exception amongst the serous membranes—the pleura, pericardium, meninges of the brain, being often the seat of primary phlegmasiæ.]

III. Puerperal Peritonitis. — The peritoneum is very liable to become inflamed in the puerperal state, those portions especially connected with the uterine organs. The uterus or its appendages are generally the first parts that become affected, and the morbid action spreads by contignity or continuity to the general surface of the peritoneum; it consequently usually exists complicated with an inflammatory affection of one or more of the textures or organs belonging to the uterine system. This subject has been already fully considered in the article Puerperal Fever.

to which we refer for details; but puerperal females may be affected with peritonitis in its simple form, when it presents some peculiarities deserving attention. Its predisposing causes are the high degree of irritability of the system which exists subsequent to parturition, and more especially in the peritoneum, from the sudden abstraction of distension which it undergoes by the contraction of the uterus after the expulsion of the fœtus. M. Chomel observes that the repeated friction to which the peritoneum is subjected during labour may account for the primitive development of peritonitis in those cases where it appears without inflammation of the uterus. (Dict. de Médecine, art. *Péritonite.*) Dr. Burns remarks that those who have suffered from uterine hemorrhage after delivery are most liable to this disease. (Midwifery, p. 526.) The affection may also be excited by violence during parturition, by the application of cold, or the injudicious use of stimuli. When it occurs during the prevalence of puerperal fever, it appears evidently to owe its origin to an epidemic cause, and in some instances to be communicated by contagion. It may therefore be considered as occurring under two forms, 1. as a sporadic disease, and, 2. as an epidemic. (See Fever, Puerperal.)

1. *Sporadic puerperal peritonitis* sometimes becomes developed a few days after parturition, but occasionally two or three weeks intervene, and in some cases the pulse continues frequent from the time of delivery till the accession of the inflammation. The first symptom that manifests itself is generally pain in the abdomen, which is usually preceded or accompanied by rigors; and Dr. Denman (Denman's Midwifery, p. 433, 6th edition,) observes that from the violence and duration of the shivering, we may generally estimate the danger of the succeeding disease.

The abdomen becomes exquisitely painful on pressure, and this symptom is usually accompanied by vomiting, thirst, sharp, small, frequent pulse, and white dry tongue. The symptoms are in fact, generally speaking, the same as those which ordinary peritonitis presents, with some modifications, however, derived from the peculiar state of the affected parts induced by parturition. The pain more especially occupies the hypogastric region, and when it extends to other parts of the abdomen, it still continues most intensely in this situation, indicating that the peritoneal covering of the uterus is principally affected. The abdomen becomes distended more rapidly and to a greater extent than in the other forms of the disease, owing to its not offering so much resistance in consequence of its relaxed state subsequent to delivery; but it does not present quite so much hardness and tension as in ordinary cases. The lochia are diminished or suppressed. The lacteal secretion is either not established or is arrested, and the breasts consequently either do not swell, or collapse after having been swollen. The disease generally runs a short course, and rarely terminates in the chronic state. When it terminates favourably, the abdominal tumefaction subsides as rapidly as it had before augmented; the lochial and lacteal secretions are re-established; the pain abates, and the vomiting ceases; the pulse becomes fuller and slower, and the other signs indicative of termination by resolution, which have been already described, are exhibited.

The fatal termination is characterized by the increase of abdominal tumefaction, pain, and tenderness, quick irregular pulse, Hippocratic countenance, cold extremities, and sometimes by the sudden cessation of pain, while the other unfavourable symptoms continue. Dr. Gordon has related some cases which terminated by suppuration; in two instances the matter escaped externally by the umbilicus, and in a third by the urethra.

2. *Epidemic puerperal peritonitis* may be considered as a variety of puerperal fever, which has by some been thought to depend in every instance on inflammation of the peritoneum; but it has been already demonstrated that various forms of uterine inflammation may occur in this fever, and give rise to a variety of symptoms, and that these local inflammations may exist independently of each other, though they are frequently combined. (See Fever, Puerperal.)

When this fever excites peritoneal inflammation, it is not, according to Dr. Gooch, "one uniform disease, but may occur under different forms; it is sometimes so mild as to be curable by the gentlest aperients, and at other times is very obstinate and fatal. In this latter form it sometimes consists of acute inflammation of the peritoneum with inflammatory fever, which bears and is curable only by early and active depletion; sometimes of inflammation and fever of a low type, in which depletion is useless and even pernicious." (On Diseases of Females, p. 14, 15.) He observes "that in the leading circumstances of the disease there is certainly a great uniformity: it almost always commences a few days after delivery, is marked by pain and tenderness of the belly, and a rapid pulse; and if not cured, terminates fatally within a week, and after death commonly leaves the depositions and effusion of inflammation: thus far it is very uniform, but no further." (P. 33.) He describes the leading symptoms of the epidemic of 1812—which he witnessed—to be "diffused pain and tenderness, with some swelling of the abdomen, a quick pulse, which was generally at first full and vibrating. Sometimes it was small, but still it was hard and incompressible; the skin was hot, though not so hot as in other fevers; the tongue was white and moist; the milk was suppressed. As the disease advanced, the belly became less painful, but more swelled, and the breathing short; towards the end, the pulse was very frequent and tremulous, and the skin covered with a clammy sweat: even in this state the tongue continued moist and the mind clear, and death took place generally about the fifth day. On opening the abdomen, which was often as large as before delivery, the intestines were found distended with air; the peritoneum was red in various parts, its surface was covered with a coat of lymph; the intestines adhered to one another, and the omentum to the intestines; coagulable lymph was deposited on various surfaces, especially in the depressions between the convolutions of the bowels and on the omentum, on both which parts it often lay in large masses; the cavity of the peritoneum contained several pints of a turbid fluid, apparently serum mixed

with lymph. In the uterus, the morbid appearances were generally confined to its peritoneal covering, which was coated with lymph, on removing which the membrane itself was found unnaturally red; but in some cases the disease had penetrated deeper into the uterus, the substance of which was sometimes infiltrated with pus, and sometimes contained small abscesses about the size of a nut; the inner surface of the uterus, especially at the fundus, often appeared black and ragged, as if gangrenous. The enlargement of the abdomen depended entirely on air in the intestines; when there was no air there was no enlargement, even though the peritoneum contained several pints of fluid." (P. 39, 40.) He describes several gradations of this affection, which have been already considered in the article PUERPERAL FEVER.

We have been induced to make this long quotation, in order to demonstrate that puerperal peritonitis, when epidemic, is nearly identical in its symptoms and post-mortem appearance with the common form of the disease. The peculiarities which it presents it possesses in common with the sporadic form, occurring after parturition, from which it only differs in its epidemic and occasionally contagious origin, in its frequent complication with uterine affections, and in being attended, in some instances, with a fever of a typhoid character. It appears to us that the epidemic form is primarily a fever that excites peritoneal inflammation which is to be considered as symptomatic of a constitutional affection; and that the sporadic form is an idiopathic inflammation, modified by the peculiarities of the puerperal state.

This view accords with Dr. Armstrong's ideas on the nature of this disease. He states that puerperal fever "is a common or specific fever, occurring in the puerperal state, and modified, like almost every other affection, by the condition of the patient at the time of the attack. In general," he further observes, "it is a common fever combined with inflammation of the abdominal and pelvic viscera, but it is sometimes genuine typhous fever, occurring in the same state, and then superadded to the symptoms of peritonitis, are developed, rapidly for the most part, those symptoms by which a fully formed typhus can be recognized." (Armstrong's Morbid Anatomy, p. 96.) Dr. S. Cusack, of Dublin, in his paper on puerperal fever, (Edin. Med. and Surg. Journ. January, 1829,) observes that the low form of puerperal fever which exhibits a typhoid character was sometimes epidemic, and that the seasons which appeared to favour its occurrence are such as give rise to typhous fever, erysipelas, and diseases of a low type." It appears, therefore, to originate from the same causes as epidemic fevers, to exhibit the same constitutional symptoms, with only this peculiarity, that the uterine organs or peritoneum are in every case inflamed, an effect which we might, *à priori*, expect in the event of fever attacking a puerperal female.

IV. VARIETIES OF PERITONITIS.—This disease presents several modifications in addition to those above described, which being attended with some peculiarities with respect to their causes, symptoms, and progress, are deserving of separate consideration. The principal of these are: 1. hemorrhagic peritonitis; 2 erysipelatous peritonitis; 3. peritonitis from intestinal strangulation; 4. latent peritonitis; 5. partial peritonitis; 6. peritonitis from perforation of the intestines; 7. peritonitis from paracentesis of the abdomen.

1. *Hemorrhagic Peritonitis*, [*Hémapéritonirrhagie* of Piorry.]—This form of the disease is very rare: its predisposing causes appear to be a sanguine temperament, and a constitution liable to hemorrhagies and inflammatory affections. If in such persons any irritation acts peculiarly on the abdominal serous membrane, an hemorrhagic action may be determined to its vessels, and a sanguineous effusion thus takes place into the peritoneal cavity without any rupture of vessels. The symptoms of this variety are similar to those of acute peritonitis. The pain, however, appears to be much more violent, and to be characterized by marked intermissions: the anxiety is greater; it is accompanied with pyrexia, a pulse at first strong and inflammatory, which afterwards becomes expanded and soft, and finally, at the approach of death, quick and small. The disease runs a very rapid course, and convulsions, with coldness of the extremities, precede the fatal termination. (Broussais' History of Chronic Phlegmasiæ; by Hays and Griffith, vol. ii. p. 182.)

2. *Erysipelatous peritonitis.*—This variety appears to owe its cause to the transference of erysipelatous inflammation from the skin or mucous lining of the throat and fauces to the peritoneum: its symptoms, as described by Dr. Abercrombie, are "sometimes slight and insidious, but sometimes very severe, and they are chiefly distinguished by the rapidity with which they run their course, and by a remarkable sinking of the vital powers, which occurs from an early period, and often prevents the adoption of any active treatment: a remarkable circumstance in the history of the affection is its connection with erysipelas and other diseases of an erysipelatous character." (On the Abdominal Viscera, p. 182.)

In one case which he relates, the day after the disappearance of erysipelas from one of the lower extremities, acute pain attacked the region of the stomach, which, in a short time, moved to the lower part of the abdomen, and around the umbilicus, with little tenderness on pressure, but accompanied with great anxiety and restlessness: the patient sunk rapidly, and died twenty-four hours after the attack. Dissection discovered a considerable quantity of bloody sanies in the abdomen, part of the small intestines of a dark red and part of a dull leaden colour, and the whole were considerably distended.

The form in which the throat is primarily affected seems occasionally to owe its origin to an epidemic cause. Dr. Abercrombie relates that in the spring of 1824 it prevailed as an epidemic in the Merchants' Hospital in Edinburgh. Its leading features were a slight erysipelatous affection of the throat, beginning with vomiting and slight fever: in some cases the internal fauces were covered with aphthous crusts or swelling of the uvula, and in some cases there were angry ulcerations about the lips, with sponginess of the gums, the larynx was unaffected in every case, and, excepting in two instances, which proved fatal by the supervention of abdominal inflammation, the

symptoms were mild, and little treatment was necessary. In the two cases referred to, the patients were attacked with the above symptoms, and, when recovering, pain and tenderness in the abdomen and serious constitutional disturbance supervened, and proved rapidly fatal. The two fatal cases render it probable that the erysipelatous action may invade the peritoneum as well as the membrane of the mouth, and that its symptoms and history sufficiently distinguish it from common peritoneal inflammation. The post-mortem appearances were peculiar, consisting of a bloody serum or pus mixed with shreds of a flaky matter, but without much or any of that inflammatory or adhesive exudation which forms so prominent a character of peritonitis in its common forms.

3. *Peritonitis from intestinal strangulation.*—This form may arise from internal or external strangulation of a portion of intestine. It presents for some time obscure symptoms, the inflammation being at first limited to a small space, and it extends itself gradually from that portion of peritoneum which is strangulated to the rest of the membrane. When the whole peritoneum becomes affected, this variety presents the same general appearance as ordinary peritonitis: it differs, however, not only in the exciting cause, but also in the succession of the phenomena which it presents; in exhibiting some symptoms which accompany it in its whole course; by its termination, and by the mode of treatment which it requires.

In this variety constipation and vomiting are frequently the first symptoms which appear, to which pain succeeds; febrile paroxysms do not, however, develope themselves till after the last symptom, or even later. In the whole course of the malady, the constipation and vomiting, the irregular form of the belly, the parietes of which are elevated in several points above the obstacle, give a peculiar aspect to this variety of peritonitis. It is much more dangerous than ordinary peritonitis, and in treating it we ought to have more in view the removal of the exciting cause which still continues to operate than the management of the inflammation itself." (*Chomel*, Dict. de Médecine, tom. xvi. p. 326.)

4. *Latent peritonitis.*—Nearly all the characteristic symptoms of peritonitis may be absent, and yet the disease exist and be productive of serious effects, and even terminate fatally. This will be most apt to occur in patients of feeble powers and advanced age, in maniacal persons, or in those affected with some severe malady, which may either absorb the attention of the physician, or mask, by its greater intensity, the peculiar symptoms of peritonitis. In such cases, it may steal on without pain or any accompanying pyrexia, and the only criteria by which we can judge of its existence, are perhaps the expression of the countenance, and, on a close examination, some degree of tumefaction and tension of the abdomen, and, occasionally, an obscure sensation of pain excited by pressure.

5. *Partial peritonitis.*—This affection may be confined to a small portion of the peritoneum during its whole course. This variety may be caused by a contusion or wound penetrating into the abdomen, or it may succeed to a surgical operation, in which the abdominal parietes or viscera are concerned; while in some instances it may arise without any apparent cause. It often commences without rigors, by a pain in a limited point of the abdomen, augmented by pressure, often accompanied with some tumefaction or hardness in the affected part, and occasionally with febrile symptoms of some intensity; but in general the vomiting and alteration of the countenance, which so frequently attend general peritonitis, are absent. It may, however, become general, and then it will present the same phenomena as the common form of the disease. When it remains circumscribed, it commonly terminates favourably in a short time, the effusion, then small in quantity, being absorbed. In some instances, the inflamed portion becomes the seat of a collection of pus circumscribed by adhesions, which may escape into the stomach or intestines by erosion of their parietes where they have formed an adhesion to those of the abscess. M. Chomel supposes that in most of those cases where, after signs of local peritoneal inflammation, pus is discharged from the stomach or intestines, it owed its origin to this source. Several forms of local peritonitis have been described by authors. Dr. Cullen mentions two, neither of which, however, he ventures to discriminate by any characteristic symptoms.

The peritonitis *omentalis* he tells us affects the omentum, and the peritonitis *mesenterica* the mesentery. (Synopsis Nosologiæ Methodicæ, tom. ii. p. 109.) Dr. Mason Good informs us that the omental peritonitis is characterized by a more sensible swelling in the region of the omentum. (Study of Medecine, 1st edition, vol. ii. p. 371.) The same author describes mesenteric peritonitis as being attended with a pain deeper-seated, and more immediately in the mesenteric region, the external tenderness being less than in the other forms. Frank states that it is accompanied with deep pain in the back and in the umbilical region, that it often terminates in abscess, which may obstruct the bowels by mechanical pressure, or open into the cavity of the abdomen, or into the intestines. (*Frank*, De Curandis Hominum Morbis, lib. ii. ord. iv. gen. 1.) Frank also mentions a variety of local peritonitis confined to the lining of the abdominal muscles, which, when limited to the covering of the rectus, sometimes causes the shape of that muscle to be developed, and effusion of lymph or blood into its sheath, with tension, distension, and occasionally speedy gangrene. When, also, the general peritoneal lining of the abdominal muscles is inflamed, the sensibility to pressure will be very great, and if it terminates in suppuration, an immense collection of purulent matter may form between the peritoneum and muscles, stimulating ascites. The same author also states, that when the peritoneum covering the bodies of the vertebræ is inflamed, it will give rise to pain in the back, in the situation of the lumbar vertebræ, much increased by the erect position of the body, and resembling in some respects disease of the kidney. When the peritoneal covering of the psoas and iliacus internus is inflamed, pain is felt in the region of those muscles, extending through the groin to the thigh, which cannot be extended without an increase of suffering, but is unattended

by any difficulty in passing the urine or fæces. Dr. Abercrombie describes several symptoms of peritonitis, which seem to arise from the inflammation having its seat more peculiarly in the serous envelope of certain organs. When the covering of the liver is affected, the case can scarcely be distinguished from acute hepatitis. When it occurs in the neighbourhood of the kidney, Dr. Abercrombie thinks it may give rise to true ischuria renalis, proving fatal by coma and effusion in the brain.

These varieties of peritonitis are interesting in one point of view, as they enable us to explain the predominance of certain symptoms in individual cases, and an attention to them may, in some instances at least, prevent our mistaking affections of the peritoneum for diseases of the organs which it covers, and may also be a useful guide as to the local treatment.

6. *Peritonitis from Perforation.*—For an account of this variety, we refer to *Peritonitis from perforation of the serous membrane.*

7. *Peritonitis from Paracentesis.*—In this variety the pain is generally first perceived in the point where the puncture was made. The flaccidity of the abdominal parietes, and the rapid tumefaction of the belly which occurs when peritonitis arises from this cause, bear some resemblance to the phenomena which puerperal peritonitis exhibits. This form has almost invariably a fatal termination; in most cases that we have seen, it ran its course in a few days, and was attended with greater prostration of strength, and less of febrile excitement than the common form of the disease.

V. Chronic Peritonitis.—When acute inflammation of the peritoneum continues beyond the fifteenth or twentieth day, it generally becomes chronic: this species of the disease may, however, arise primarily from the exciting causes we have before enumerated, operating on a patient of advanced age or debilitated constitution. Particular occupations which cause pressure on the abdomen, may predispose to or excite this disease, to which may be added cold and moisture, prolonged residence in hospitals, fatigue, unwholesome food, protracted intermittents, and any kind of slow effusion into the cavity of the abdomen.

We shall consider chronic peritonitis under two heads: 1st, *primitive*, without being preceded by symptoms of acute inflammation; 2d, *consecutive*, following as a consequence of acute peritonitis.

1. The primitive form may commence in a slow and almost insensible manner, without presenting any very obvious symptom. There may not be any abdominal pain at its commencement or during its course, and it may only exhibit the appearance of simple ascites: in many cases we cannot ascertain with any certainty its presence during life, but when it is more open in its characters, they are identical with the consecutive form, the symptoms of which vary considerably in the early stages. It is in general attended with some abdominal pain, which is mostly deep, not very acute, and rarely permanent; in many cases the patient only complains of pain when his abdomen is pressed either by the hand or the action of the surrounding muscles, or on a sudden shock of the body. There is occasional vomiting and more or less distension of the abdomen, which sometimes becomes tympanitic; and in some cases indurated spots can be felt, which are tender to the touch. Emaciation, irregular bowels, either constipation or diarrhœa, or the one alternating with the other; increasing distension of the abdomen, and inability to bear even the pressure of the ordinary dress if at all tight; various dyspeptic symptoms, and general debility, mark the progress of the disease. The alvine evacuations are sometimes of a pale colour and peculiar fœtor, in other instances of a dark appearance, and sometimes nearly natural. (*Abercrombie*, p. 192.)

Dr. Pemberton observes that there is no tension of the skin of the abdomen, as in the acute species; on the contrary, that the skin and abdominal muscles sit loosely upon the peritoneum, which gives a sensation to the touch, as of a tight bandage underneath, over which the skin and muscles may be said, as it were, to slide. (On Diseases of the Abdominal Viscera.)

In some patients the appetite is often preserved, and the digestion is but little deranged, in which cases we may conclude that the peritoneum reflected over the stomach is not very deeply involved in the disease. Broussais mentions the sensation of a ball rolling about in the abdomen, and sometimes approaching the throat, which he attributes to the agglutination of the intestines, these forming, with the gorged mesenteric glands, a round and mobile mass in the belly, often without any effused fluid. (Lond. Med. Chir. Review, Sept. 1820, p. 170.)

The general phenomena are very obscure: the pulse is often natural, except towards evening, when it becomes quick, with increased heat of skin, and slight flush on the cheeks, and occasionally some dyspnœa and cough. Dr. Pemberton, however, observes that though the pulse is somewhat accelerated, and the tongue, particularly in the morning, slightly covered with a white fur, with considerable thirst, he never observed any exacerbation of fever in the evening, or any hectic flushes on the cheeks: on the contrary, the countenance is full of languor, and the face is pale and doughy.

In some forms of the disease, the abdomen becomes augmented in volume, yields a dull sound on percussion on a part or the whole of its surface, and occasionally presents the sense of fluctuation more or less obscure, with an œdematous swelling limited to the inferior extremities or parietes of the abdomen. (*Chomel*, Dict. de Médecine.) In other forms, the abdomen rather diminishes than augments in volume, and offers an unnatural resistance on pressure, with, occasionally, some degree of projection near the umbilicus, occasioned by the intestines matted together in a mass before the bodies of the vertebræ.

With more or less of these symptoms, the disease advances slowly, and sometimes remains stationary for several months, and even may in some cases present some temporary amendment; but it generally terminates fatally, either by the supervention of acute peritonitis or enteritis; or the patient sinks from exhaustion, the result of long-continued irritation or diarrhœa. In some instances, ascites precedes the fatal termination, or purulent

effusion into the abdominal cavity takes place, which may escape outwardly by the umbilicus or inguinal ring: or the tubercles which have been developed on the peritoneal surface may ulcerate, and form a communication between the intestines and cavity of the peritoneum, with escape of the contents of the former into the sac of the peritoneum, inducing acute peritonitis, which proves rapidly fatal; or disease of the mesenteric glands may be induced, and the patient dies in a state of marasmus with hectic symptoms.

The **diagnosis** in this disease is extremely obscure, and is rather to be deduced from a close consideration of the history of each case, the predisposing and exciting causes, and the assemblage of local symptoms, than from any definite rules.

Its **prognosis** in general is unfavourable. M. Broussais, in an early edition of his work, considered it as incurable; afterwards, however, he met with several cases which terminated favourably. Dr. Abercrombie succeeded in curing some cases in individuals whose families had formerly suffered from this affection. Dr. Pemberton states that the symptoms which indicate recovery are an abatement of the pricking pains in the abdomen, and a diminution of the frequency of the pulse to eighty in a minute; but that under these favourable appearances a relapse is always to be dreaded.

Morbid Anatomy of Peritonitis. — The alterations which the peritoneum presents after death from this disease, are essentially the same as are found in cases of inflammation of other serous membranes. The morbid effects are greater or less, according to the intensity and duration of the disease. They are sometimes confined exclusively to the peritoneum, evidencing that this membrane may be partially or generally inflamed, without the subjacent tissues being affected: however, in some of the complicated forms of this disease, morbid lesions of the other intestinal tunics will be occasionally discovered to coexist with those characteristic of peritonitis.

The following are the effects of inflammation of the peritoneum, as far as they are revealed by dissection: — 1. increased vascularity and thickening of the peritoneum; 2. effusion of coagulable lymph, either in the form of flocculi, membranes, bands, or masses; 3. effusion, into the peritoneal cavity, of various fluids, serum, pus, or blood, mixed or separate; 4. gangrene; 5. tuberculous formations; 6. granulations on the peritoneal surface; 7. ulceration.

1. *Morbid appearances in acute peritonitis.*— The first effects of a low degree of inflammatory action upon serous membranes appear to be simply an increased deposition of the serous fluid; and in this manner it is probable that a certain state of these membranes, which, if not actually inflammatory, closely borders upon it, is sometimes relieved; the increased quantity of fluid being afterwards absorbed, and the parts recovering their healthy relations. (*Abercombie*, p. 3.)

When inflammation is fully established, its earliest effect is increased vascularity, which produces at first a slight degree of opacity of the membrane, and red points begin to appear on its surface, which may either occupy a small portion, or cover nearly the whole extent of the peritoneum; the surface of which at this time appears dry and shining, but on touching it an unctuous coating will be detected. Sometimes, instead of the red points, blood-vessels are developed, forming red striæ more or less numerous. As the inflammation advances, the small points become multiplied, coalesce, and form patches of variable extent, and the blood-vessels become more evident and numerous. In a more advanced stage, the redness is rendered more intense, and occupies a larger portion of the membrane; sometimes forming broad surfaces of inflammation, which run like bands along the course of the intestines, and are bounded by the adhesions which different portions of the bowels contract with each other. This redness is frequently arborescent, sometimes intermixed like network. The vascular injection has been supposed by some to exist in the arterial capillaries; but Dr. Armstrong observes, that whatever may be the case during life, it is after death chiefly seated in the venous capillaries; for on a minute inspection, the small ramifications of the arteries may be seen empty, traversing the intermediate portion of intestine, like so many transparent lines. The degree of redness is ultimately influenced by the quantity of secretion being greater in those cases where there is least serum and lymph.*

Along with this redness we observe more or less thickening and opacity of the peritoneum; an effect produced not only by the hyperæmia of the inflamed part, but also by the effusion of serum, lymph, or both, into the subserous cellular tissue, which causes some degree of pulpiness, and a facility in separating the serous coat from the subjacent parts. The serous membrane itself is also thickened by the effused fluid penetrating between its laminæ, and separating them more or less from each other, and in some instances a slight degree of emphysema exists, from the disengagement of air in the connecting cellular tissue; but when the inflammation is slight, this thickening is not apparent.

The intestines are much thicker and more massy, as well as the mesentery and the mesocolon; and the omentum sometimes is rendered as thick as a person's hand; effects which arise from the extravasation of coagulable lymph into the cellular substance between the laminæ of peritoneum which forms them. (Baillie's Morbid Anatomy.

Redness and thickening may be considered as

* M. Scoutetten asserts that this redness, when intense, is not owing to the distension of the blood-vessels, but to a sanguine exudation which is formed on the surface of the peritoneum, and which adheres strongly to it; and that the surface is uniformly red, and appears villous. Both causes probably concur to produce the effect.

Bichat, M. Gasc, and others, have asserted that the absence of redness on the peritoneal surface after death may occur in cases where the membrane was inflamed during life. M. Scoutetten, (Archives Générales, tom. iii. p. 501,) however, from some experiments he has performed on living animals, has come to a contrary conclusion: he asserts that the disappearance of redness from an inflamed *external* surface after death is owing to the pressure of the atmosphere, which has but a very modified influence on an *internal* tissue; and that, consequently, the characters of inflammation are very nearly the same in those tissues during life and after death: his experiments are highly ingenious, and would seem to justify the conclusion he has deduced from them, viz. *that an inflammation of an internal membrane will in every case leave increased redness after death.*

the first effect of peritoneal inflammation; but it is accompanied or quickly followed by effusion of serum and lymph, which have been supposed to be separated simultaneously. Dr. Armstrong, however, seems to think that the lymph is first effused; but it would appear that the degree of intensity of the inflammation determines the nature of the effusion. When the inflammation is not very violent, serum seems to be the earliest product of the vessels of the affected part; but if the inflammatory action is very acute, lymph is often thrown out in the first instance. This effusion of lymph may take place a very short time after the commencement of inflammation; it is at first soft and gelatinous, afterwards becomes more consistent, and finally assumes the texture of a membrane of considerable tenacity. It generally soon becomes organized: Andral (Clinique Médicale,) observes that in some cases, twenty hours after the commencement of peritonitis, vessels can be traced and injected in this fibrous concretion, which has become a living texture; in other cases, after several months, no trace of organization can be found in these membranous layers. This coagulable lymph may assume various forms; it may either be deposited in a lamina of variable thickness, lining the peritoneal surfaces, agglutinating the intestines to each other, to the abdominal parietes, or to the omentum; or narrow bands of membrane, of variable length, may connect two or more coils of intestine together; or a mass of lymph of a prismatic form may lie between the intestinal convolutions, filling up their interstices, the anterior flat surface of which mass corresponds to the parietes of the abdomen, and the two other surfaces, slightly concave, are applied on the two contiguous intestines, and terminate in their interval by a rounded angle. The lymph may also be in the form of flocculi, or small shreds of membrane, floating in a serous fluid, or deposited on the free surface of the peritoneum when little or no fluid is found.

These false membranes are either of a white colour, grey, or sometimes a little reddish; they vary in their thickness from a quarter to two or three lines. When the inflammation has lasted twenty or thirty days, these adhesions acquire a considerable degree of firmness; they are often productive of no inconvenience, but if very numerous, and uniting the coils of intestine very closely together, they may give rise to a modification of the form of the belly, an habitual tension in the abdomen, and more or less disturbance in the digestive functions. Dr. Abercrombie relates some cases where fatal ileus seemed to be induced by the operation of such causes, which appeared to act by deranging the muscular power of the intestinal canal, or by inducing a strangulation of a portion of intestine.

Serous effusion, as we have before observed, may take place very early in this disease;* but in general it is not considerable in quantity until the affection has existed for some time. This, however, is not always the case: in some instances, after thirty-six or forty hours, there is a large quantity of fluid effused; it is generally accumulated in the inferior parts, unless retained in distinct cavities by adhesions. Its colour varies very much; it is sometimes limpid; and that is principally the case when the peritonitis has been partial:† at other times it is whitish, greyish, milky, or yellowish, and occasionally has all the sensible properties of pus. Dr. Abercrombie observes, that the opaque milky deposition is commonly connected with alteration of the structure of the membrane, which in such instances presents a soft thickened appearance, resembling a part that had been boiled. The more common appearance of the peritoneum consists of a deposition of false membrane, coexisting either with the milky flocculent fluid, or with pus, or a fluid entirely limpid. In the latter case the deposition on the surface of the membrane will prevent the re-absorption of the fluid; so that the accumulation which might otherwise have disappeared will thus become a permanent cause of ascites, provided the disease does not prove speedily fatal. (*Abercrombie*, p. 3.)

This effusion is sometimes reddish, evidently from a mixture of the colouring matter of the blood; and in the hemorrhagic variety of peritonitis, large quantities of blood in a coagulated state have been found by M. Broussais in the peritoneal cavity, without any rupture of vessels being detected, accompanied with extensive ecchymoses of the cellular tissue which unites the peritoneum to the contiguous parts.

The quantity of fluid effused in peritonitis varies from a few ounces to several pounds; its consistence is sometimes that of water, without containing any albuminous clots; at other times it equals that of milk or the pus of the cellular tissue, and often contains the flocculi before mentioned.

The peritoneum is seldom found in a state of gangrene in its whole extent; but eschars of variable size, and of a greyish slate-colour or bluish, are formed, which are easily lacerated, and exhale a fetid odour. The surface of these eschars is often covered with a greyish soft matter, little adherent, which appears to be the commencement of decomposition: these eschars sometimes pervade the entire thickness of the intestinal tunics, or the great epiploon, or extend deeply into the abdominal parietes.

There are certain brownish, black, or violet degenerations of the peritoneum which have been mistaken for gangrene, but are only the results of chronic irritation; they are easily distinguished by not being readily torn, by being destitute of the gangrenous odour, and by the great extent to which the peritoneum is discoloured, the entire membrane being sometimes affected. These appearances are a common consequence of chronic peritonitis.

Ulceration very rarely occurs as a consequence of peritonitis; though not unfrequently the peritoneum is perforated in cases where the ulcerative

* In some cases of peritoneal inflammation the secretion of this membrane is suspended, and it appears dry.

† Bichat observes that, when serous effusions are the consequence of an affection of a viscus, the serosity is limpid, transparent, and probably of the same nature with that which is exhaled in its natural state; but that on the contrary, when the effusion depends on inflammation of serous membranes, the fluid is almost always altered. (*Roche et Sanson*, Elemens de Pathologie, tom. i. p. 552.)

process, commencing in the mucous membrane, erodes the other coats of the intestines; this naturally leads us to consider peritoneal ulcers as of two kinds:—1. *primitive ulcers*, or those which occur primarily in the peritoneum as a direct consequence of inflammation; 2. *consecutive ulcers*, or those which originate in the intestinal mucous membrane.

There are not many cases on record of primitive ulceration of this membrane. M. Scoutetten observes, that if the patient is not exhausted, and continues to live for some time, crosions of the peritoneum, at first slight, become by degrees more and more deep, and are converted into true ulcers, which may extend and destroy all the membrane, and even the subjacent tissues. (Archive Générales, tom. iv. p. 392.) In a patient who had suffered from a venereal affection, and had experienced pains in the lumbar region, most severe at night, M. Portal found, on examination of the abdomen after death, several ulcers covered with pus in the peritoneum situated on the anterior of the lumbar vertebræ and of the kidneys. The same author cites Bouet and Paw as having seen subjects in whom the peritoneum appeared eroded to a great extent. (Anatomie Pathologique, tom. v. p. 126.) M. Scoutetten observed the diaphragmatic portion of the peritoneum ulcerated in one case to the extent of two inches; and there is a case also mentioned by the same author, in which, after symptoms of peritonitis, the abdominal parietes were perforated at the umbilicus, and a whitish fluid of the consistence of pus escaped from the abdomen. We have before mentioned, in treating of partial peritonitis, that purulent effusions in this form of the disease occasionally escape by an opening into the stomach or intestines; from this we would infer that ulceration of this membrane may occur more frequently than is generally supposed, but there are not many cases of this description on record.

Consecutive ulceration is much more frequent, and will be fully considered in the article *Peritonitis from perforation of the serous membrane.*

2. *Morbid appearances in chronic peritonitis.*—The organic changes which are the consequence of chronic peritonitis are very nearly the same as those which result from the acute form. There are some peculiarities, however, belonging to the chronic species which deserve attention. In chronic peritonitis, the redness, the result of increased vascularity, is of a darker hue, and the larger branches of veins are more considerably dilated. (*Armstrong*, p. 76.) The peritoneum has acquired a greater thickness, and the inflammation appears to have penetrated to the subjacent membranes and organs. The false membranes are very numerous and firm, and unite many coils of intestine; sometimes they form a kind of envelope which surrounds the great epiploon and the intestines, and sometimes partial pouches are formed by false membranes which contain a quantity of fluid: when these membranes are detached, we find the subjacent peritoneum less red than in acute peritonitis. In some subjects scarcely any liquid is found: in these cases the false membranes are less abundant and less thick; and the intestines are united to each other by the adhesions which the inflammation has caused them to contract, and not by intermediate albuminous layers. (*Scoutetten*, Arch. Gén. tom. iv. p. 387.)

In some subjects, on the other hand, a considerable quantity of effusion is found without any false membrane on the peritoneum, which is thickened, reddish, and exhibits a multitude of dilated blood-vessels. The epiploon is red, thick, and fleshy, and sometimes contains between its laminæ transparent vesicles like hydatids, and substances resembling granulations are occasionally seen on its surface.

When the peritonitis has been of several months' duration, it sometimes occurs that the abdominal parietes are not distended by effusion, but are pressed close to the intestines. The epiploon is covered with a crowd of whitish tubercles of variable size, surrounded with blood-vessels more or less developed. These tubercles may also exist on any part of the peritoneal surface: Dr. Armstrong has found them under three modifications, 1. as small miliary points semi-transparent and firm; 2. as uniformly opaque bodies of a larger size and nearly of the colour and consistence of the kernel of the ripe horse-chestnut; and, lastly, as soft white substances, not unlike cut portions of the medullary matter of the brain. The first and second modifications are seated in the subserous cellular tissue, and likewise between the mucous and muscular intestinal coats; but the soft medullary variety appears to be formed in general on the free surface of the serous membrane itself. (Morbid Anatomy, &c.) Tubercles at first are extremely minute, but they gradually increase in size and number, and sometimes coalesce: they occasionally exceed the size of a large pea. When small, they are of considerable consistence, and adhere with such tenacity to the peritoneum, that they can only be separated by tearing this membrane; but as they increase in magnitude, they become softer, and approach in their appearance to pus, when they can be easily detached. After being softened, they may again become indurated, and are sometimes converted into a calcareous matter. Occasionally, when they have existed for a considerable time, the peritoneum in the intervals between the tubercles becomes of an obscure red colour, or bluish or black, and presents a strong contrast with the white appearance of the tubercles. These bodies may ulcerate and give rise to perforation of the intestines; when tubercles exist, there is generally only a small quantity of fluid in the abdomen, which may be of different shades of colour from a grey to a black. In most instances, where they have been found on the peritoneum, they existed simultaneously in other organs, especially the lungs. If the symptoms which characterize a tuberculous diathesis coexist with signs of chronic inflammation or irritation of the peritoneum, we may have some reason to suspect a tuberculous state of this membrane.

M. Bayle has described certain bodies which he calls *granulations*, presenting a pisiform white appearance, and being of a hard consistence, not unlike miliary eruptions of the skin; but M. Broussais supposes they are nothing more than a transformation of the exuded matter which passed

from a liquid to an organized state. (History of the Chronic Phlegmasiæ of Broussais, by Hays and Griffith, vol. ii. p. 294.)

Chronic irritation may produce several other morbid changes on the peritoneum or the subserous tissue, the detail of which would include nearly the whole of the morbid anatomy of this membrane. It may become cartilaginous, bony, or scirrhous. The mesenteric glands may become diseased and tuberculous. Broussais has found vesicles resembling hydatids, and extensive lardaceous depositions, in the subserous cellular tissue. This fatty matter was not only deposited under the peritoneum, but also between the laminæ of the mesentery and omentum; it was of a white or yellow appearance like tallow, and mixed with a gelatino-albuminous fluid of thinner consistence and darker colour, which gave the whole mass a mottled appearance. He supposes this the result of chronic inflammation of the subserous tissue, but whether those productions are always to be considered the effects of inflammatory action is doubtful. They at all events are not the usual results of this state; and it appears necessary that a peculiar disposition to such formations must pre-exist in the constitution, which may be called into action, and determined to any particular structure or organ by the existence of chronic inflammation or irritation there.

M. Scoutetten* has described a morbid appearance, which he considers as peculiar to primitive chronic peritonitis. It consists of a number of greyish spots formed by little points, the number and close propinquity of which determine the intensity of the colour of the spots, which are sometimes brown or even of a black hue. These spots vary in number, and are sometimes only a line, and in other instances, an inch in extent. They are occasionally accompanied with an increased development of vessels. [M. Andral (*Cours. de Pathologie Interne*) regards the black patches as melanic.] Minute yellowish vesicles are also sometimes seen, and an abundant serous effusion almost constantly coexists, in general transparent, because the inflammation has not been sufficiently active to change entirely the mode of secretion.

Treatment.—The general principles of treatment which are applicable to other internal inflammations are equally so to this; with some modifications, however, arising from the nature of the texture affected, and from its relations to the organs which it covers. We shall first consider the treatment of this disease in the infant, and afterwards in the adult, and lastly speak of the management of chronic peritonitis.

1. *Treatment of infantile peritonitis.*—Our principal remedy in infantile peritonitis is the abstraction of blood, either general or local. In an infant under six months, though general bloodletting may often be required, yet a sufficient quantity can usually be obtained by the application of three or four leeches to the hand or foot, where we can easily control the hemorrhage, which cannot be done so effectively if the leeches be applied to the abdomen. Applied to the extremities they are nearly as efficacious in removing local inflammation in infants, as when applied to the vicinity of the part affected. They seem to produce the same result as a general bloodletting, as the face and lips become pale, the pulse falters, and syncope followed by vomiting occasionally takes place. These effects are apt to be produced when general bloodletting is carried to a considerable extent; and sometimes a state of nervous agitation and general commotion is induced, which, if not speedily removed, may terminate in death. The best remedies in a case of this kind are the horizontal position, cool air, and a drop or two of the tincture of opium. (*Dr. Cuming*, Transactions of the King's and Queen's College of Physicians in Ireland, vol. v. p. 49.)

Where general bloodletting is practised, from two to three ounces may be abstracted from an infant between six and twenty months old; at two years from three to four ounces; and when the age is above four, about five, six, or eight ounces may be drawn according to circumstances. After the inflammatory action is lowered by the abstraction of blood, advantage will be derived by establishing and keeping up an open state of the bowels, but we should avoid effecting this by irritating medicine. Small doses of calomel alone, or combined with a little of the pulv. corn. ust. cum opio, if the stomach is irritable, followed at intervals by castor oil or emollient enemata, will in general be found to answer sufficiently well. Fomentations to the abdomen will tend much to relieve the pain, and should be often repeated, and continued for some time; or we may put our little patient for a few minutes in the warm bath. If it is judged necessary to apply counter-irritation to the abdominal surface, warm flannel sprinkled with turpentine appears to us much preferable to blistering, as it produces a sufficient rubefacient effect, without the injurious consequences which blisters often produce on infants. The recommendation of M. Billard to remove the child from the breast, appears to us questionable. The sudden alteration in diet would be very apt to produce derangement of the stomach or bowels, a complication which would add to the danger of the patient. If the acute symptoms subside, and it seems probable from the continuance of abdominal tumefaction, slight dyspnœa, quick weak pulse, dry tongue, and hot skin, that the affection has passed into the chronic state, we should suspend or be sparing of evacuations: a leech or two to the abdomen may occasionally be necessary. The strength is to be supported by animal broths, arrow-root, &c.; the bowels regulated by calomel in the combinations above recommended, according to circumstances. The warm bath may be occasionally useful; also counter-irritation to the abdominal surface, and in some cases mercurial inunction.

Treatment of peritonitis in the adult.—Acute peritonitis, though generally attended with considerable danger, yet in the greater number of cases admits of a cure by active and early treatment. The following are the indications which we should have in view: 1. to reduce the action of the heart and vascular system; 2. to diminish the hyperæmia of the affected part; 3. to allay local and ge-

* Archives Générales, tom. iv. p. 398. We have been much indebted to this author for information on the morbid anatomy of the peritoneum. This essay contains more information on this point than any author we have consulted.

neral nervous irritation; 4. to restore the secretions to a natural state, and to excite the peristaltic action of the bowels; 5. to relieve urgent symptoms. Copious and early bloodletting are the most efficient means we can employ for the reduction of vascular action. This is indeed the principal therapeutic agent in this disease, in which it can be employed to a greater extent than in inflammation of mucous surfaces. Its efficacy is greater according as it is used early, and carried to such an extent as to make a decided impression on the system. The quantity abstracted is to be regulated by our estimate of the capability of the patient's constitution to bear depletion, and not by any arbitrary rule of quantity. We have seen five or six ounces produce as decided an effect on a delicate female as thirty ounces on a robust patient. We should take the blood from a large orifice, and allow the stream to flow either until the pain is relieved, or weakness of the pulse, paleness, and tendency to syncope is induced; the apparent debility which the patient exhibits in the onset of the disease is not to deter us from active depletion. The pulse commonly rises after venesection, and becomes fuller and softer, and the patient feels relieved and lightened, rather than exhausted by its employment. The advice which Dr. Abercrombie gives on the employment of bloodletting in this disease we have experienced the value of in many cases: viz. "to follow up the first bleeding by small bleedings at short intervals, when the effect of the first begins to subside: in this manner we prolong, as it were, the impression which is made by the first bleeding, and a twofold advantage arises from the practice — namely, that the disease is checked at an early period, and that the quantity of blood lost is, in the end, much smaller than probably would be required under other circumstances: if we allow the patient to lie after the first bleeding ten or twelve hours, or even a shorter period, the effect of it is entirely lost, and a repetition of it, to the extent of twenty ounces, may be required for producing that effect upon the disease, which by a former method might be produced by five. And, besides, the disease has been in the interval gaining ground, its duration is protracted, and the result consequently rendered more uncertain. The inflammation of a vital organ should not be lost sight of for above an hour or two at a time, until the force of it be decidedly broken; and unless this takes place within twenty-four hours, the termination must be considered as doubtful."

[In these cases, the combination of free bloodletting with opium, as advised under another head, (see Narcotics,) is often of the most marked advantage.]

The efficacy of bloodletting will depend in a great measure on its early employment, but we are not to abstain from it altogether at even an advanced period of the disease. If we have not been so fortunate as to see our patient in the commencement of the attack, still if the state of collapse has not been formed, if there is still some pulse and heat of surface, with abdominal pain and tenderness, we may abstract a moderate quantity of blood from the system with a chance of producing a good effect; or in debilitated patients apply leeches: but when the symptoms indicative of sinking are present, it would be obviously improper to take blood either generally or locally, as it would only hasten the fatal termination, and bring undeserved reproach on a valuable remedy.

Having reduced the general vascular action by the lancet, our next object should be to diminish the quantity of blood in the affected part by local bleeding, which will also assist in keeping up the constitutional effect produced by venesection. Gooch, (Diseases of Females, p. 45,) has well observed, "that as long as the pulse is quick, full, and hard, it is in vain to take blood from the affected part; if we could completely empty its gorged capillary vessels, they would be instantly gorged again, whilst the heart and large arteries are injecting them with so much violence. On the other hand, after having reduced the force of the general circulation, the capillary vessels of the part often remain preternaturally injected. This I conclude from the fact that the patient is often not relieved till local bloodletting has been used, and then is relieved immediately."

Having allowed the patient to recover from the faintness produced by the general bleeding, the abdomen should be slightly fomented with warm water, wiped frequently dry, and leeches should be applied in numbers proportioned to the urgency of the symptoms and strength of the patient. They should be especially concentrated over the parts where most pain and tenderness on pressure exist; and after they have fallen off, fomentations with cloths dipped in warm water should be assiduously applied and repeated for some time, which will both encourage the bleeding and soothe the irritation of the inflamed parts. The application of leeches may be repeated several times, as long as any considerable soreness remains.

Either before or during the application of the leeches, and as soon as possible after the vascular action has been reduced by venesection, from five to ten grains of calomel combined with one or two of opium should be administered, which may be repeated in diminished doses every three or four hours. By this combination, the constitutional and local irritation consequent on the inflammation, and which has a tendency to aggravate it, will be allayed by the narcotic; and the secretions, which have been more or less suspended or deranged, will be restored by the mercury, which modifies its action, and determines it to the skin, and is also supposed to equalize the circulation. After the second or third dose of this medicine, the bowels may be opened by mild aperients, aided by enemata: castor oil, in doses of from half an ounce to an ounce in some aromatic water, may be given if the stomach is not irritable. If vomiting is urgent, the Rochelle salts with the subcarbonate of soda, in a state of effervescence with lemon-juice, may be used in repeated doses, so as to produce a moderately laxative effect. Strong purgatives are highly injurious, and even a small dose of castor oil may exasperate the disease, if used previously to depletion. Having evacuated the bowels, the use of the calomel and opium should be resumed, and continued till the mercury has affected the system. As soon as salivation is established, we have generally found the symptoms become much mitigated, and our experience accords with that of

Dr. Gooch, who remarks that whenever the gums were affected in this disease, the patients invariably recovered. The establishment of mercurial action not only assists in subduing the inflammation, but may prevent or remove those effusions of lymph which afterwards form adhesions that are often the source of future mischief.

In addition to these means, the warm bath may occasionally be useful, or repeated fomentations to the abdomen will tend much to relieve the pain and soreness. Counter-irritation, by means of blisters, after local and general bleeding, is generally recommended; but we have not been much in the habit of employing them. While much inflammatory excitement prevails, they would prove injurious, and at any period of the disease their application would deprive us of the most important means we possess of ascertaining the degree of tenderness by pressure. The application of warm flannel dipped in turpentine we conceive a good substitute, and it will generally produce a rubefacient effect.

Oil of turpentine, which was first recommended by Dr. Brennan of Dublin, in puerperal peritonitis, may be useful internally in certain forms of the disease, but we conceive it requires to be used with caution; it acts as a powerful cathartic, and at the same time excites the general system; hence it would obviously prove injurious, while much heat of skin, frequent pulse, and indications of active local inflammation were present; but in a debilitated patient, after the acute symptoms have been subdued, or in cases of puerperal peritonitis accompanied with typhoid symptoms, or where general and local bleeding cannot, from the delicacy of the patient's constitution, be carried to the requisite extent, it may be employed with advantage.

During the whole course of our treatment, the strictest antiphlogistic regimen should be observed. Light farinaceous diet, in small quantities, and rice or barley-water for drink, are most suitable for the patient; but if symptoms indicative of a sinking of the vital powers should appear, wine and other tonics may be necessary. Dr. Abercrombie used injections of beef-tea and cinchona with advantage.

When we have carried venesection to a considerable extent, and have reduced the vascular action to such a degree as renders the abstraction of more blood inadmissible, if we still find pain and tenderness present, the exhibition of a full opiate, followed by fomentations or a warm poultice to the abdomen, will sometimes remove the symptoms. If vomiting is urgent, it may sometimes be checked by saline draughts with tincture of opium, or by leeching and blistering the epigastrium. When the pulse continues very frequent after the inflammation appears to be subdued, Dr. Abercrombie recommends the use of digitalis.

A tympanitic state of the abdomen at an advanced period of the disease may occur from mere loss of tone, after the inflammation has been subdued. Small quantities of wine or brandy may be given at short intervals. Frictions of the abdomen, and injections of beef-tea, bark, or sulphate of quinine, turpentine, or tincture of assafœtida, with a moderate quantity of laudanum, may be repeated every two or three hours. The bowels may be moved with mild laxatives, such as aloetic wine, or aloes and hyoscyamus, but laxatives require to be given with the utmost caution. The authorities for the tobacco injection in inflammation of the bowels are numerous: among others, De Haen, Fowler, Abercrombie, and Howship, have recommended this remedy; the latter author relates three cases in which, having tried bleeding, the warm bath, and stimulating injections without effect, the fume of tobacco cautiously injected caused a general commotion and rumbling noise in the bowels, which was soon followed by copious evacuations of fæcal matter. The patients were all saved. (Practical Observations, p. 19.)

During convalescence the greatest care is necessary in order to prevent a relapse. The patient should observe the strictest temperance in his diet, and return with great caution to the use of animal food or wine. The bowels should be kept regular, the feet warm, and flannel worn next the skin for a long time after every symptom has disappeared.

Treatment of Chronic Peritonitis.—Chronic inflammation of the peritoneum, when far advanced, is in most cases incurable, especially when the false membranes and other morbid productions are considerable in quantity, or when it coexists with a tuberculated state of the peritoneum or subjacent cellular texture, such substances being for the most part incapable of absorption; but where the effusion consists of serum, with but little or no solid productions, our chance of success is greater. Much will depend on arresting the disease at an early stage, at which time a degree of subacute inflammation often exists, which will require, with some modifications, the same treatment as the acute form. At every period in this disease, when the abdominal pain and tenderness are present, and the constitution of the patient is not very much debilitated, blood may be abstracted from the system to the extent of six or eight ounces at a time, which may be repeated twice a week until those symptoms have disappeared. The application of leeches also may be frequently adopted; this will be found the most effectual mode of relieving the abdominal soreness. All fæcal accumulations should be prevented, and the bowels kept regular by the gentlest aperients or enemata, but active purgatives should be avoided, as they may be productive of serious evil. The warm bath or fomentations to the abdomen may be frequently employed, and will assist much in allaying irritation and pain, and in determining to the surface. Blisters may also occasionally be applied to the abdomen, or the external application of turpentine, as recommended in the acute form, will be found useful in relieving the abdominal tenderness.

The antiphlogistic regimen is to be observed to a certain extent, and light nutritious diet, composed principally of the farinaceæ and milk, in limited quantities at a time, appears the most suitable. Muscular exertion, or pressure on the abdomen, will be found to aggravate the symptoms, and are of course to be avoided; but in some cases gentle exercise in a carriage will promote the general health. A sea voyage has been recommended, and may be useful.

During the whole course of the disease we are to guard against the supervention of acute inflammation, which may be induced by a very slight exciting cause, and is especially to be dreaded, as the patient, from his debilitated state, could not bear the evacuation which would be necessary for its removal. When the pain and soreness are mitigated, if serous effusion exists, its absorption will be promoted by diuretics. Digitalis, either in the form of infusion or tincture, may be given conjoined with the alkalis and the spirit of nitric ether; but care should be taken to excite as little irritation of the stomach or intestines as possible. We have found the ioduretted ointment of Lugol, mixed with equal parts of mercurial ointment, applied by friction to the abdomen, a powerful means of exciting absorption in cases of ascites consequent on peritonitis. In some instances it surpasses our expectation in producing the complete removal of considerable ascites in a few weeks. We have also in some cases exhibited at the same time internally the aqua mineralis iodinæ of the same author, and found it a valuable auxiliary. Broussais strongly recommends the introduction of diuretic medicines, such as the tincture of cantharides or squill, by means of friction on the skin, and it may be proper to try this mode of exciting diuresis, when, from irritability of the stomach, we cannot give diuretics internally. Anodynes may occasionally be necessary, and we should select those which do not produce constipation, such as hyoscyamus or conium. Rigid abstinence has been recommended as a means of producing absorption, (Med. Chirurg. Rev. Sept. 1820. p. 187,) and in some cases perhaps it may be tried, but it will be improper where the patient is much debilitated by a protracted disease. Where all inflammatory symptoms have subsided, and a state of exhaustion remains while the effusion continues, tonics combined with diuretics may be cautiously tried. We have in such cases derived considerable advantage from the exhibition of the ferrum tartarizatum in solution, combined with the spiritus junip. comp.: it appeared to improve the patient's general health, and excite the action of the kidneys at this period of the disease. The antiphlogistic regimen will require to be relaxed a little, and more nutritious diet in small quantities may be allowed.

D. H. Mac Adam.

VI. Peritonitis from Perforation of the Serous Membrane. — This most severe and generally fatal form of peritonitis is the result of a solution of continuity of the peritoneum, which may arise from various causes, and occur in various portions of the sac. In most cases the result of this accident is the introduction into the sac of the peritoneum of some solid or fluid substance which produces a sudden, and generally universal, inflammation, so that the principal characters of this form of disease are, the suddenness of the attack, the terrible rapidity and violence with which the disease runs to its fatal termination, and its resistance to ordinary medical treatment. It will be found that in some of the cases, the particulars of which will be detailed, all these peculiarities were not observed, but we shall find, notwithstanding, that the above characteristics will apply to the disease in general. The following are the most common causes of the accident: — 1st, external injuries, either of the solid or hollow viscera of the abdomen, or of the parietal peritoneum merely; 2dly, rupture of the bladder from distension, and of the uterus during parturition; 3dly, rupture of some portion of the digestive tube, from the gelatinous softening of its coats; 4thly, ulcerative perforation of the serous membrane, arising either from disease in any part of the subdiaphragmatic portion of the digestive tube, from suppurations of the solid viscera opening into the peritoneum; from ulceration of the bladder or ovaries; or from perforation of the diaphragm by purulent collections on its thoracic surface.

If we examine these different causes with respect to their frequency, it is plain that from the first order arise most cases of the disease. In this order,—which includes surgical operations on the peritoneum, — the introduction of irritating substances into the peritoneal cavity is by no means a necessary occurrence, although, in the case of rupture from external violence, we see the worst examples of this formidable occurrence; for, as will appear presently, the opening in such case is generally much more extensive, whereby the quantity of matter introduced comes to be greater, and the closure of the orifice much more difficult.

In the present article we shall principally consider that form of peritonitis which results from perforation of the tunics of some portion of the digestive tube,—an occurrence in the great majority of cases, the result of circumscribed ulceration of the mucous membrane and glands. The study of this form of the disease tends to elucidate those cases which arise from other causes.

It is necessary to remark, in the first place, that ulcerative perforation of the intestinal tunics does not necessarily imply a consequent effusion of the contents of the tube into the peritoneal cavity; for it may happen in many chronic and even in some acute cases, that in consequence of adhesions being formed between the two surfaces of the peritoneum, at a point corresponding to the situation of the ulcer, the contents of the tube are prevented from escaping into the general cavity. Thus, the serous membrane covering the opposite fold of intestine, or some of the solid viscera, may come to form the base of an ulcer which originally was wholly unconnected with it. Again, it may happen that this new base to the ulcer may in its turn give way, and an unnatural communication be thus formed between two essentially different portions of the tube, and the fæcal contents pass across the serous membrane, but not enter its cavity. A remarkable case of this description is described by Dr. Abercrombie. The patient, who was fifty-six years of age, had laboured for two or three weeks under impaired appetite, languor, and occasional pain in the abdomen, when he was suddenly seized, while walking, with vomiting of fæcal matter, but felt no other inconvenience until about a week after, when a similar attack recurred; he was then seen by Dr. Combe, who found him looking unwell, but with a natural pulse and good appetite. The bowels were easily regulated, and no signs of organic disease could be detected. After this time the vomiting returned at various intervals, sometimes three or four times a day, and sometimes he was

free from it a week at a time. The matter ejected always consisted of pure fæces, sometimes so consistent that it was brought up with difficulty until he diluted it by swallowing hot water. During the course of this affection, the body continued regular or easily regulated, and the matter vomited completely resembled that which was passed from the bowels. No tumour could be detected by examination; his appetite continued good, and he was never observed to vomit food or other matters taken into the stomach. In this state he lived for three months, and died gradually exhausted, without any particular change in the symptoms, except that a week before his death he vomited a considerable quantity of blood. On dissection, the stomach was found contracted and adhering to the parietes of the abdomen on the left side, and to the arch of the colon. At the place of the adhesion a soft tubercular mass was formed, which seemed in general to be about two inches in thickness. The stomach appeared externally healthy; internally it showed a mass of ulceration which occupied the whole of the great curvature, and covered about one-half of its inner surface. The pylorus and whole pyloric extremity were healthy. In the centre of the ulcerated part there was a ragged irregular opening fully two inches in diameter, which made a free communication with the arch of the colon; and around the opening there was also some ulceration of the mucous membrane of the colon. The intestines in all other respects were healthy. The small intestines were empty; the caput coli was distended with fæculent matter, and the colon throughout contained healthy well-formed fæces. (On Diseases of the Stomach, &c.) Chomel has described a case in which the duodenum communicated with the colon through the medium of the gall-bladder. (*Andral*, Précis d'Anatomie Pathologique.) In another case on record, a communication existed between two loops of intestine formed by a little canal about two lines in length and eight in width, which was lined by a mucous membrane continuous with that of the intestinal tube.

Many cases are recorded of perforating ulcers of the digestive tube communicating with the solid viscera. Thus the base of an ulcer of the colon has been found constituted by the tissue of the kidney; ulcers of the stomach have been found resting on the spleen; Rayer has described an ulceration of the duodenum, the basis of which was a portion of the liver. The effusion of the contents of the stomach from ulceration is commonly prevented by the pancreas, the substance or the peritoneal coat of which forms the base of the ulcer. In this way a perfect cicatrix may be formed, and the health of the individual be preserved.

In most of these cases of perforation without effusion, a partial and very circumscribed peritonitis ensues, which, by its adhesions, prevents the escape of the contents of the intestine. It is further to be remarked that this occurrence is commonly the result of a chronic disease, so that time is afforded for the exudation and organization of lymph. But we are not to conclude that this adhesion always takes place in chronic ulcerations; the contrary is the fact, as will be shown presently. In recent ulcerative perforations, effusion of the intestinal contents is, as might be expected, the almost constant result; but we have seen a case where not only one but several perforations, the result of recent ulcerations, occurred, and yet where no effusion of fæcal matter took place. The following are the particulars of this remarkable case.

A young woman was admitted into the Meath Hospital in the beginning of the year 1829. She had enjoyed good health until thirteen days previous to her admission, when she was attacked with cough, followed on the next day by symptoms of fever. She complained of cough and dyspnœa; there was great prostration of strength, the skin was hot, and the tongue covered with a white paste. She took saline purgatives and effervescing draughts without relief. Headach and deafness supervened.

Two days before admission she complained of pain in the epigastric region, which was removed by leeching. On the 24th of January, the day of her admission, she had intense bronchitis. Respirations 40, and pulse 130 in the minute. There was great restlessness, and the belly was tympanitic. For the next nine days all her sufferings seemed referable to the chest; but on the 2d of February she had a certain degree of tenderness in the epigastric region. This was again removed by the use of leeches, and for eleven days there was no prominent abdominal symptom; but the distress of respiration and the signs of bronchitis continued without alleviation. The exhibition of tartar-emetic was now resorted to; and though it produced vomiting, yet the thoracic symptoms improved so much, and without any sign of abdominal disorder, that great hopes were entertained of her recovery. The skin became cool, the pulse fell to 100, and the deafness gradually disappeared. On the 12th of February, however, there was a severe relapse. The thoracic symptoms became again violent, *with some epigastric* tenderness. She sank on the following day.

On dissection, the lungs were found filled with miliary and granular tubercles; in some places hepatized, and presenting signs of intense inflammation in the bronchial mucous membrane. A small quantity of sero-purulent matter was found in the cavity of the pelvis. The small intestines were glued together by flakes of unorganized lymph; and on separating their folds, we discovered four perforations, each sufficiently large to admit a quill. These corresponded to recent ulcers in the muciparous glands, which had perforated all the coats of the intestine, and, in fact, rested on the serous membrane of the opposite fold. No fæcal matter whatever was discovered in the cavity of the peritoneum.

We here see a case where, from recent disease, no less than four large perforations occurred without any fæcal effusion; a circumstance explicable by the formation of lymph around each of the orifices, which we must suppose to have taken place prior to the giving way of the serous membrane at the base of the ulcers. Accordingly, the usual symptoms of peritonitis from effusions of the contents of the intestine did not occur. The glueing together of the small intestines, and the fluid in the pelvic cavity, must be then considered as re

sulting from the extension of the different (at first local) inflammations of the serous membrane; a circumstance not to be wondered at when we consider that the disease was acute, the fever high, and the points of irritation of the serous membrane numerous. How far the latency of the abdominal inflammation is to be explained by the coexistence of intense thoracic disease, we shall not now inquire.

Peritonitis from perforation of the intestinal tube, and effusion of its contents, is, as might be expected, almost always a violent and fatal disease. It is violent, because it arises from the introduction of a highly irritating fluid into the sac, and dangerous in the highest degree from the seat of the inflammation; it is, moreover, kept up by the continued ingress of fæcal matter through the perforation, and derives further malignancy from having supervened in a subject already attacked by another disease. In fact, although in a few cases the patients have shown some power of resistance to the disease, and have lived for several days from the occurrence of the accident, yet these cases may well be considered as exceptions.

But are we to believe that the effusion of the intestinal contents is inevitably followed by a violent and acute peritonitis? A case recorded by Andral is in opposition to this opinion. It was that of a young person labouring under phthisis, through whose umbilicus a round worm (*ascaris lumbricoides*) was discharged. He lived for several weeks after this occurrence, and during each day a small quantity of fæcal matter escaped through the umbilical fistula. On dissection a chronic peritonitis was discovered, and the serous cavity contained a fetid fluid quite similar to that which had passed through the umbilicus, and in which were several lumbrici.

It is obvious that such a case as this, though of great rarity, is not without its analogies in other systems. We know that the occurrence of a pulmonary fistula is not necessarily followed by violent symptoms; that the pleuritis may be so latent as that the period when the fistula was formed shall be quite uncertain. As a general proposition, then, it may be stated that in both the peritoneum and pleura a fistula, through which foreign substances pass into the sac, may form without violent symptoms or acute inflammation. These cases, however, are exceptions to the general rule; and the cause of the absence of acute inflammation in such instances is still to be sought for. Perhaps the anæmic state of the body, as in phthisis, may have some influence.

When we examine the different diseases in which, at some period, a sudden change in the physical relations of parts takes place, we observe, in most cases, that this sudden change is accompanied by striking symptoms, the suddenness of which leads to the diagnosis. For example, the paralysis, which is the result of an apoplectic effusion, comes on suddenly; and by this is distinguished from that from softening of the brain, which comes on gradually. Again, a patient has a recognised aneurism of the aorta: if he drops down dead, the great probability is that an internal rupture of the tumour has occurred. If the signs of an abscess of the liver suddenly disappear, with copious expectoration, or with a diarrhœa, a vomiting, or a peritonitis, we diagnosticate a solution of continuity, an opening into the lungs, the digestive tube, or the peritoneum. When a tubercuious or other abscess opens into the pleura, the empyema and pneumothorax are ushered in by new and violent symptoms. The same observations apply to the diagnosis of rupture of the uterus and bladder.

Now, although cases of exception may be met with in every one of these diseases, yet they are so rare that the general applicability of the diagnosis — as drawn from the suddenness of new symptoms — is not much infringed on. Apoplexy may occur with gradual symptoms. We have already stated that a tuberculous abscess may perforate the pleura without violent symptoms, and so on. On the other hand, suddenness of invasion of new symptoms may be observed without any solution of continuity. Yet both the want of suddenness and violence of symptoms in cases of rupture, and their occurrence where no solution of continuity exists, are to be looked on as exceptions to a general rule.

We shall now detail some examples of peritonitis from perforation of different portions of the digestive tube. "A young woman, aged eighteen, had been affected for about six months with variable appetite and occasional pain in the stomach, which made her frequently sit with her body bent forward, and her hand pressed upon the epigastric region. Little notice was taken of the attacks, as she was going about, and otherwise in good health; and for some weeks previous to the attack now to be described, her appetite had greatly improved. On the 26th of November, 1824, while in a room by herself, she was heard to scream violently; and when a person went into the room, she was found unable to express her feelings, except by violently pressing her hand against the pit of the stomach. When she was soon after seen by Mr. M'Culloch, she was moaning as if in extreme agony, but was unable to speak. The pulse was 86, and very weak. She could scarcely swallow; but soon after vomited the contents of the stomach, which seemed to be merely food which she had recently taken. Various remedies were employed without relief. She continued with every appearance of extreme suffering till seven o'clock in the morning of the 27th, when she said the pain was considerably easier, but was still very severe in the pit of the stomach, and was extending downwards over the abdomen. The abdomen was now becoming distended; and when we saw her, about three o'clock in the afternoon, it was distended to the greatest degree, and very tense. The pulse was extremely feeble; she was scarcely able to speak, but her countenance was expressive of extreme suffering. Nothing afforded the smallest relief, and she died about two in the morning—twenty-nine hours from the attack. *Inspection.*—The cavity of the peritoneum was distended with air, and likewise contained upwards of eight pounds of fluid of a whitish colour and fetid smell. There was slight but extensive inflammatory depositions on the surface of the intestines, producing adhesions to each other and to the parietes of the abdomen. On the upper part of the small curvature of the stomach near the cardia, there was a small perforation of

a size which admitted the point of the little finger. Internally, this opening communicated with an ulcerated space on the mucous membrane about the size of a shilling, with slightly thickened and hardened edges, and a considerable perpendicular loss of substance. The stomach in all other respects was entirely healthy." (Abercrombie, Researches on the Diseases of the Stomach, &c. p. 35.)

We have given this case at full length, as it may be considered as an example of the mode of inflammation of the serous membrane in these cases, both as to invasion and termination. In this case, and in some to which we shall just now allude, the perforation was the result of a chronic but circumscribed irritation. In another case described by Dr. Abercrombie, the peritonitis suddenly supervened in a subject apparently affected with chronic dyspepsia, in which the prominent symptoms were severe pyrosis and occasional vomiting. In consequence of a careful regulation of regimen, the stomach had recovered its healthy functions, and the patient's general health had become excellent; but he was obliged to observe great caution in regimen, from the occasional recurrence of slight attacks of his former symptoms. During one of these slight attacks, he was suddenly seized with excruciating pain in the pit of the stomach, some vomiting, coldness of the body, and a small frequent pulse. No relief was afforded by treatment, and death took place in thirty hours from the attack. On dissection, extensive recent peritonitis was shown, and a perforating ulcer of the stomach near to the pyloric portion. The stomach, with the exception of the perforating ulcer, and another, the base of which was formed by the surface of the liver, was perfectly healthy. (Op. cit. p. 37.)

In this case there can be little doubt of the connection between the primary symptoms and the ulcer, the base of which was formed by the surface of the liver; and in all probability there would have been a permanent cure, had not the second ulceration occurred.

In almost all the cases of this form of peritonitis, resulting from a perforation of the stomach, symptoms of a chronic disease of this organ had preceded the accident for a greater or less space of time. Of these, local pain and vomiting were the most frequent, but the degree of severity of these symptoms, and their effect on the general health, were exceedingly various. In some of these cases a cancerous ulceration existed; in others, the affection of the stomach was a simple circumscribed ulcer; while in a third class, the disease was the gelatinous softening (*ramollissement gelatiniforme*) of the French authors.*

The immediate cause of the accident in by far the greater number of these cases, was the progress of the destructive process; but in two, the effort of vomiting seemed to be the cause of the solution of continuity. Andral describes a case of an individual who laboured under the symptoms of a cancerous disease of the stomach, and who was suddenly seized with peritonitis during the act of vomiting, which had been brought on by an emetic. On dissection, a perforation of the stomach was found in the centre of an old ulceration of the stomach. (Précis d'Anatomie Pathologique, tom. ii.)

In another case on record, an old ulcer had existed, and had formed adhesions with the pancreas. The perforation took place during the efforts at stool, and was found to have occurred at one of the extremities of the above-mentioned ulceration. (*Bouillaud*, Archives de Médecine, tom. i.)

It is admitted that in some cases a perforation of the stomach takes place in individuals who were in the enjoyment of the best health; and that on dissection no evidence of a previously existing *ulceration* of the organ could be found. Here the absence of gastric symptoms, previous to the fatal attack of peritonitis, is not extraordinary. But even a fatal ulceration of the stomach may occur with singular latency, as in a case recorded by Dr. Abercrombie, where, in a strong and healthy-looking girl, sudden and rapidly-fatal peritonitis supervened. On dissection, a perforating ulcer was found in the smaller curvature, all around which the coats of the stomach were found greatly and extensively thickened. *This girl had been residing in the house in which she died for four months, during which she was never known to complain of her stomach, or to show the smallest deviation from the most robust health.* (Op. cit. p. 41.) It appeared, however, that she had had fever some months before this; and in all probability this fever was symptomatic of, or connected with, a gastritis.

We shall now proceed to examine what appears to be the most common case of this disease, namely, that in which it supervenes on a perforating ulcer of the lower portion of the ileum. In the great majority of these cases, the ulcerations were recent and the disease acute. In many of them, symptoms of a previous excitement of the muciparous glands were observed.

As Louis is the author who has drawn the attention of pathologists more especially to this disease, we cannot do better than quote from his memoir (Recherches Anatomico-Pathologiques. Paris, 1826) the results of his observation of the first eight cases which he describes. "The patients who have been the victims of this disease were young and vigorous, with the exception of the first, who was weak and of a lymphatic temperament; they had a good constitution, were rarely ill, not addicted to excess, and presenting a sanguine, a bilious, or a lymphatigo-sanguine temperament. Almost all had been but a short time in Paris. The causes of their disease were unknown. If we except a single case, it commenced as a slight, continued fever, and presented no severe symptom before the period of the perforation; in but one patient was there a severe diarrhœa, which was, however, of short continuance; in another, it had been moderate; still less in the subjects of the second and sixth cases, and not occurring in the remainder. Those with whom the diarrhœa was for a short time severe, had slight pains in the epigastrium and more severe pain in other portions of the abdomen, while in the remainder they were very slight, or not at all pre-

* See *Gerard*, Des Perforations Spontanées de l'Estomac — *Travers*, Medico-Chirurgical Transactions — *Crampton*, Ibid.—Journal Gen. de Medecine, 1821.—Dr. *J. Crampton*. Transactions of the Association of the King's and Queen's College of Physicians, vol. i.

sent before the period of perforation. Three of them believed themselves convalescent, and were considered so for some days, when the symptoms of this lesion occurred. A fourth seemed to have been cured rapidly of a slight enteritis; so that not only in these four subjects nothing occurred which could lead to the anticipation of the disease under which they sank, but it would have been absurd, from the mildness of their symptoms, to have apprehended any serious consequences. And at this moment we have before us the history of many patients who have died from an acute perforation of the intestine, and who, with this exception, presented no symptom which could distinguish them from analogous cases where there was a rapid return to health.

"If the period of the formation of these ulcerations cannot be accurately determined, we shall scarcely be far from the truth in supposing that it coincides with the first symptoms of the disease, from which it would result that the progress of these ulcerations has been very rapid, and that they have arrived at their last period in from twelve to twenty-five days, rarely later.

"At a certain period of the disease, on account of which the patients had entered the hospital, they experienced suddenly an exquisite and tearing pain of the abdomen, rapidly followed by alteration of the features, nausea and vomitings, &c. &c. These symptoms continued with greater or less violence from twenty to fifty-four hours, presenting remissions which were more or less well marked, and indicating a most intense peritonitis, produced by a violent cause acting in a sudden manner, just as occurs when an irritating substance is applied to the surface of the peritoneum. It is by the reunion of these signs that the lesion that now occupies us has been recognised by MM. Lerminier, Chomel, and Martin Solon, under whose care the patients were. From these circumstances it appears that we may regard the following as characteristic signs of perforation of the intestine: *if in an acute disease and in an unexpected manner a violent pain of the abdomen suddenly supervenes, if this pain is exasperated by pressure, accompanied by rapid alteration of the features, and more or less promptly followed by nausea and vomiting, we may believe and announce that there is a perforation of the intestine.*"

This author further remarks, that the most intense pain of the belly suddenly supervening, and accompanied by alteration of the countenance, nausea and vomiting, will be insufficient to allow us to make this diagnosis with certainty, unless the pain is exasperated by pressure. It is not only necessary that this character should exist, but also that the pain shall extend rapidly to the whole abdomen, so that, if it remains confined to the point where it has first occurred, we cannot, notwithstanding the coincidence of other symptoms, declare that the intestine is perforated, or that any other viscus has opened into the cavity of the abdomen. In illustration of this he states the case of a man who had laboured under symptoms of chronic gastritis, when he was suddenly attacked with violent pain in the epigastrium, soon followed by nausea, vomiting, and alteration of the countenance. This pain, which was exasperated by pressure, was confined to a very small space, where it first occurred. It continued, along with the other symptoms, for four days, when the patient died, and on dissection was found to proceed from an aneurism of the cœliac artery, which had ruptured, and caused an effusion of blood behind the peritoneum.

It is not always that the pain, though occurring under the above circumstances, continues until death. In one of the cases of this lesion, which occurred at the Meath Hospital, there was complete cessation of pain and even of tenderness for many hours before death. The patient declared himself much better, yet the other symptoms of peritonitis continued, such as the coldness of the extremities, the rapidity of the pulse, the swelling of the belly, and the Hippocratic expression. In three of Louis's cases the same circumstance was observed; the countenance continued altered, the nausea and vomiting persisted, the surface was pale and of a violent hue, and the patients were perpetually shivering and covering themselves carefully up in the bed-clothes. They resembled persons who, having taken a cold bath, cannot again regain warmth.

We may be further assisted in the diagnosis of perforation of the small intestine by the seat of the pain as it first occurs. This is generally in the ileo-cœcal region; but it may no doubt be felt in other situations, according to the place of the perforation and the disposition of the intestine.

We have now witnessed a considerable number of these cases, which occurred under our observation in the wards of the Meath Hospital. In nine of these cases the diagnosis of perforation of the intestine was made, and proved to be accurate by dissection. It is scarcely necessary to remark that the general features of these cases were the same, namely, *the sudden supervention of the symptoms of peritonitis, and the rapid sinking of the vital powers.*

In three cases, the serous inflammation supervened during the existence of gastro-enteric fever more or less well marked.

In one case, the symptoms came on on the seventh day of a catarrhal fever.

In two cases, the disease occurred after symptoms of acute enteritis, which in one of the cases followed a severe debauch.

In one case (which we have before mentioned), the perforations, though numerous, yet did not produce any well-marked symptoms, the patient dying apparently of acute phthisis.

In one case, the symptoms occurred after an hypercatharsis induced by an over-dose of salts. The same cause appeared to produce the disease in another patient, who recovered under the use of large doses of opium, and to which we shall hereafter allude.

In several of these cases there had been previous diarrhœa, which was suddenly checked at the time when the perforation appeared to take place; but in one of them in which this had occurred, a copious purging of natural coloured fæces came on twelve hours before death. This patient had used calomel freely the day before.

Another remarkable symptom was the irritation of the bladder, showing itself by sudden inability to pass urine, and constant efforts at micturition

This irritation of the urinary organs occurred in several cases, and in two was the very first symptom observed. The bladder was found inflamed in one case; while in another it was merely contracted and empty, with its mucous membrane pale. This was remarkably the case in a patient who was admitted in December 1830. This man had enjoyed uninterrupted good health until three days previous to admission, when, on getting up in the morning to gratify the extreme desire to pass water, he found himself unable to do so, the attempt putting him to intolerable torture; he had pain in the region of the bladder, not so severe when he was not attempting to pass urine. The pain continued during that day, but towards night became more easy, and he passed about ten ounces of urine; still all the attempts at micturition were attended with considerable suffering. On admission he presented the general appearance of a person affected with peritonitis: he had acute pain in the right lumbar region, and great tenderness in the umbilical, right iliac, and hypogastric regions. What he complained of principally was retention of urine; yet the catheter showed that the bladder contained but a few drops of turbid high-coloured urine, and that the urethra was unobstructed. Towards evening, after the use of an injection and venesection, he passed a small quantity of urine, the countenance was Hippocratic, and the patient died at three o'clock on the following morning. On dissection, the usual appearances of peritonitis from perforation were seen. The perforating ulcer existed about eighteen inches from the ileo-cœcal valve. Three other ulcers existed lower down, which had not made their way into the serous cavity. The peritoneal surface of the bladder was highly inflamed.

In another case, where the symptoms succeeded a bilious diarrhœa, the sudden supervention of the pain was also accompanied by inability to pass urine. On dissection, the perforation was found large and corresponding to the fundus of the bladder. And in a third case, in which the disease appeared on the seventh day of a catarrhal fever, the first symptom of the perforation was sudden inability to pass urine. In this case a turpentine enema opened the bowels, and enabled the patient to empty his bladder. Here the opening existed about three inches above the ileo-cœcal valve, and the mucous membrane of the bladder was found highly inflamed.

In all our cases, evidences of a previously diseased condition of the mucous glands of the intestine existed to a greater or less degree; in some instances accompanied by functional disturbance, in others occurring in a perfectly latent manner. Of this last remarkable fact many other instances have been observed by authors.

The peritonitis thus supervening, as might be expected, almost always runs its course in a very short time. In the first nine cases recorded by Louis, death took place in from twenty to fifty-four hours, while in one case the patient lived seven days from the first appearance of the symptoms of peritonitis. In this instance the symptoms, which had been violent at first, became moderated at the commencement of the fourth day, and during the remaining three days the pain of the belly was very slight, and if the first symptoms had not been so well marked, doubts would have been entertained of the truth of the diagnosis. "In confirming," says Louis, "those diagnostic symptoms which we have established, this observation is of great importance as connected with prognosis, since it shows that when once the signs of perforation have occurred, we must not depart from our diagnosis and admit of hope even after an arrest of symptoms, and an apparent amelioration even of some days standing. This reserve is furthermore necessary from the fact that the lesion that brought about the perforation is not so soon arrested, and that the first perforation may be followed by a second, and even by a third. (Obs. vi. and vii.) This prolongation of life after so severe an accident is in accordance with the variations which we so constantly observe in the march of diseases, and points out the analogy between perforations of the intestines and those of the lung."

In our cases the length of time the patients lived after the occurrence of the perforation, varied from twelve to one hundred and twenty hours. We find, on examining the results of nineteen cases observed by ourselves, or recorded in the works of different authors, in which the period of the perforation could be accurately ascertained, that the average length of time that the patients lived after this accident was about twenty-nine hours. In one of our cases, however, which we have brought into this calculation, the patient lived about one hundred and twenty hours; and in a case recorded by Louis, the perforation took place on the 18th of May, and the patient lived until the 25th of the same month. The shortest period in which the fatal termination took place seems to be in six hours. We may observe, that in some of the cases which have entered into the above calculation, the perforation occurred in the stomach, and in one in the duodenum.

We have hitherto been principally occupied with those cases of peritonitis from perforation in which the symptoms were well marked, and in which the intestinal contents passed into the cavity of the peritoneum. It is a fact, however, that in a very few cases this accident may supervene without the ordinary sudden and violent symptoms: thus, in the ninth observation of Louis, we read of a patient who was labouring under fever with diarrhœa, in whom the symptoms which appeared to correspond with the perforation were delirium and shivering, which occurred in the morning and continued till the evening of the next day, when the patient sank; there was also increased meteorism, and the patient winced only after a strong pressure of the belly. In this case the perforation was not suspected, yet Louis inquires whether we might not, under similar circumstances, suspect a perforation of the intestine, particularly when it is considered that peritonitis without perforation is rare as occurring in the course of acute diseases. He thinks that if, in the course of a continued fever with diarrhœa, the patient is seized with delirium, shiverings, and a slight tenderness of the belly, which until then had not been painful, we might be authorised to suspect a perforation of the small intestine.

In the case of the young phthisical patient recorded by Andral, through whose umbilicus a

round worm (ascaris lumbricoides) was discharged, the individual lived for some weeks after this occurrence.

It must be always borne in mind that the diagnosis of peritonitis from perforation of the intestine in ordinary cases, is founded on the greater probability that the peritonitis thus suddenly supervening proceeds more from the introduction of irritating matters from the intestine than from any other cause. It is plain also, that so far as the peritonitis is concerned, we shall observe the same general symptoms in cases of the rupture of abscesses into the peritoneal cavity, or the effusion of urine from rupture of the bladder; but still a few cases may occur where a sudden and fatal peritonitis may supervene without solution of continuity of the serous membrane of the peritoneum. We need scarcely allude to strangulated hernia further than to observe that, where the strangulated portion is exceedingly small, so as not to be capable of detection by external examination, the case may closely resemble one from sudden perforation of the intestine. Of this we witnessed a very remarkable case, where a portion of the intestine not larger than a small hazel-nut had become strangulated. The symptoms supervened with sudden pain, constipation, swelling, tenderness of the belly, and the other signs of peritonitis.

In the article Hepatitis we have described a case of peritonitis from the opening of an hepatic abscess into the serous membrane; in this case the patient lived for eight days after the occurrence of the perforation; and on dissection we found the false membrane of the peritoneum in progress of organization, as shown by the existence of large blood-vessels of a deep blue colour passing through its substance, which had assumed a laminar structure.

It is scarcely necessary to remark, that the prognosis in peritonitis from the introduction of irritating substances into the cavity, must be unfavourable in the highest possible degree, for two reasons; — first, from the nature of the exciting cause, which produces a rapid and universal inflammation; and, secondly, from the previous existence of some other disease which was the cause of the perforation. Yet we believe that even under these almost desperate circumstances, we are not justified in abandoning the patient to his fate without an attempt to save life by medical treatment. We know that the peritoneum may recover from inflammation after solutions of continuity in various portions of its extent, and hence this circumstance merely, though dangerous in a great degree, is not necessarily to lead us to despair. It would seem that it is from the introduction of irritating matters into the cavity that the greatest danger is to be apprehended, and hence to prevent or diminish the extent of such an accident should be the principal object of the physician. In cases of this description the principles of treatment are, then, essentially different from those of ordinary cases of peritoneal inflammation.

In the second number of the Dublin Journal of Medical and Chemical Science, the writer of this article has shown the inapplicability of the ordinary mode of treatment of peritonitis in those cases. In most of them the powers of life sink so rapidly that bleeding, either general or local, cannot be attempted; neither can we use mercury internally, from the danger of exciting the peristaltic action of the intestine, which of course tends to keep open the communication, and causes a fresh ingress of fæcal matter into the sac; nor can we hope much from the external application of mercury, from its slow action, and the improbability of its affecting the system under these circumstances.

Yet, in a few cases, we find that the patients may live for several days, and that a process of organization of the effused false membrane may be found to have commenced; and hence the two great indications are, to support the strength of the patient so as to gain time, and to diminish, as far as possible, the peristaltic action of the intestine. In the paper above alluded to, we have proposed the use of opium in large doses for the treatment of this form of the disease, to which we were led from having witnessed the admirable effects of that remedy in low cases of peritonitis in the hands of Dr. Graves, who, eleven years ago, treated successfully two cases of peritonitis after paracentesis, and occurring in patients of a bad habit, by means of opium in free doses, and without abstracting a drop of blood. The same physician employed a similar treatment in a case of abscess of the liver opening into the peritoneal sac, and with success, as far as the cure of the peritonitis was concerned. (See Dublin. Hos. Reports, vol. 5. Dublin Journal of Medical and Chemical Science, vol. 2.)

In the paper above alluded to, we have detailed two cases, in which decided evidence of the utility of this mode of treatment was obtained. In the first, in which the symptoms of perforation had existed for two days, and the patient was in almost complete collapse, the use of sixty drops of the black drop in the twenty-four hours, was followed by most singular improvement: the pulse had become full and soft, the extremities warm, and the countenance had lost the Hippocratic expression. The patient could bear pressure on the abdomen, which the day before was exquisitely painful. The same treatment being continued for twenty-four hours longer, *every symptom of abdominal inflammation had subsided:* the belly was natural and the pulse good. At this period the mildest possible saline laxative was exhibited, which produced four evacuations, followed by an immediate return of the symptoms of peritonitis, under which the patient rapidly sank. On dissection, we found universal peritonitis, but the intestines were every where agglutinated together, except in the left iliac fossa. The perforation existed in the cæcum, and was small; and the mucous membrane of the ileum and colon was but little affected.

The interest of this case consists, first, in the decided advantage derived from the use of the opium; secondly, in the danger it shows to result from any thing that excites the peristaltic action of the intestine; and thirdly, in the verification of the diagnosis of perforation, and the evidence of a process of cure having commenced.

In the next case the disease was of three days' standing, and it supervened suddenly from a hypercatharsis, produced by an over-dose of Glauber's salts. The patient was apparently in the

last stage when the opium treatment was commenced. He was ordered a grain of opium every hour. Next day the symptoms were decidedly improved, and though he had taken twenty-four grains, he had not experienced the slightest coma, headach, or delirium. The same plan of treatment was persevered in, the daily doses of opium being gradually diminished until the tenth day, when the convalescence being completely established, the remedy was omitted. During this time, diarrhœa set in for three or four days severely; this was treated by the application of a few leeches to the anus, and the use of anodyne enemata. The patient took in all one hundred and five grains of opium, exclusive of that in the injections, without experiencing any of the usual effects of this remedy in large doses.

When we connect these facts, and recollect that, in bad forms of peritonitis, such as that occurring after paracentesis in debilitated subjects, it has been found successful, and also that its efficacy has been proved in a case where the peritonitis supervened on the introduction of the matter of an hepatic abscess into the peritoneum, it seems justifiable to recommend the exhibition of opium in free doses in cases of peritonitis from the introduction of irritating matters into its cavity. Of these cases, that from ulcerative perforation of the intestine seems to be the one most likely to be benefited by such a treatment, as in these cases the solution of continuity is but of small extent, the disease from which it has originated much more often acute than chronic, and generally confined to a small extent.

It is necessary to remark that in the treatment of these cases, the strength of the patients must be supported, and the greatest caution observed, even for some time after the symptoms of peritonitis have subsided, in the use of any thing that can excite the peristaltic action of the intestine.

PHLEBITIS. See VEINS, INFLAMMATION OF.

PHLEGMASIA DOLENS. Some of the hypothetical names which have, up to the present time, been employed by authors to designate the disease which forms the subject of this article, are —*Œdema Lacteum, Œdème des Nouvelles Accouchées, Dépôts Laiteux, les Infiltrations Laiteuses des Extrémités Inférieures, Hysteralgia Lactea, Metastasis Lactis.* As it has been demonstrated by the researches of recent pathologists that the swelling of the affected limbs, and all the other local and constitutional symptoms of this affection, invariably depend on inflammation of the iliac and femoral veins, we propose to substitute the term *crural phlebitis* for phlegmasia dolens, and the other names which have now been mentioned and were in general use before the true nature of the disease was ascertained.

We shall consider *crural phlebitis* as it is observed, 1. in puerperal or lying-in women; 2. in women who have not been pregnant; 3. in the male sex.

1. CRURAL PHLEBITIS IN PUERPERAL WOMEN.—In the works of Hippocrates, Rodericus a Castro, and Wiseman, we find obscure notices of this disease. Moriceau was, however, the first author who distinctly pointed out its characteristic symptoms, and he referred the swelling of the lower extremities to a reflux upon the parts of certain humours which ought to be evacuated by the lochia, of which he says, "le gros nerf de la cuisse s'abrouve quelquefois tellement, qu'il en peut rester a la femme une claudication dans la suite." (Traité des Maladies des femmes grosses, tom. i. 1688, p. 446.) It is not improbable, from the manner in which Moriceau has expressed himself in this passage, that he had actually felt with the finger the indurated and inflamed femoral vein in the upper part of the thigh, which he mistook, however, for a nerve, as some other observers seem to have since done, for an inflamed absorbent. When the disease was accompanied with great fever, difficulty of respiration, pain, and tension of the abdomen, he considered the affection to be dangerous in proportion to the severity of these symptoms.

A more full account of crural phlebitis was published not long after Mauriceau, by Puzos and Levret, both of whom considered the swelling of the limbs to depend on a deposit of milk in the part.

Puzos states that it is a painful and protracted, and sometimes a fatal disease, and that it occurs most frequently about the twelfth day after delivery, though sometimes as late as the sixth week. He also observed that one limb only is at first affected, and that the pain and swelling commenced in the groin and superior part of the thigh, and descend along the course of the crural vessels to the ham, and thence along the calf of the leg to the foot. He observed, likewise, that the disease attacked the other limb, and that it presented the same appearances as the first affected. The extent of the mischief, he remarks, is readily recognised by a painful cord formed by the infiltration of the cellular tissue which accompanies the crural vessels. "C'est dans l'aine et dans la partie supérieure de la cuisse, que le dépôt commence à donner des signes de sa présence par la douleur que l'accouchée y ressent; et la douleur suit ordinairement le trajet des gros vaisseaux qui descendent le long de la cuisse; elle est même plus vive dans tout ce trajet. On reconnoit l'etendue du mal par une espèce de corde douloureuse que forme l'infiltration du tissu cellulaire qui accompagne ces vaisseaux, et l'enflure se joint presque toujeurs à la douleur." (Traité des Accouchemens, 4to. p. 350. Paris, 1759.) Puzos recommended repeated venesection, cathartics, and sudorifics, and various local applications, as warm fomentations, and embrocations of oil of almonds with ammonia.

Levret's description of crural phlebitis strikingly coincides with that of Puzos, and he refers the disease to the crural vessels in so direct a manner that it is singular he did not discover its precise nature. When the disease attacks one side, a tumour more or less considerable, he observes, is found on examination in the iliac fossa. The cord of crural vessels is also painful through a great part of its course. "On distingue même

souvent, dans toute son étendue, de petites tumeurs olivaires qui l'entourent ça et là." (L'Art des Accouchemens, p. 932, 2d ed. Paris, 1761.)

In a manuscript copy of Dr. William Hunter's Lectures, taken in 1775, no account is given of this disease; but from the following note, written by Mr. Cruikshanks to Mr. Trye, at the time he was engaged in the publication of his work on the subject, it is evident that Dr. Hunter had seen cases of crural phlebitis, and was convinced that the opinions of Puzos and Levret respecting the nature of the disease had no solid foundation. "They have imputed the swelled leg, which happens after lying-in, to a dépôt de lait, but it is not: to something wrong in the constitution; the patient is first seized with pain in the groin, the pulse becomes smart, and the part becomes tender, the pain and tenderness get gradually lower down, and the muscles are stiffened into hard bumps, and an œdema frequently succeeds the inflammatory swelling. It is generally called a cold, but it is not. In some it is over in a short time, in others it will last some months; it generally does well."

In the year 1784, Mr. White of Manchester published an "Inquiry into the nature and cause of that swelling in one or both of the lower extremities which sometimes happens to lying-in women," and he suggested or adopted the opinion that the disease depends on obstruction, detention, and accumulation of lymph in the limb, or on some other morbid condition of the lymphatic vessels and glands of the affected parts. He considered it to arise from some local accident during labour, and to be a purely local disease. Mr. White saw fourteen cases, either during or subsequent to the attack; but as none of them proved fatal, an opportunity was not afforded him to determine the truth of his hypothesis by an examination of the actual condition of the different textures of the affected extremities.

An essay on the swelling of the lower extremities incident to lying-in women was published in 1782, by Mr. Trye, of Gloucester, in which he referred the symptoms to rupture of the lymphatics as they cross the brim of the pelvis under Poupart's ligament. Six cases came under the observation of Mr. Trye, and in all recovery likewise took place. He clearly perceived, although he was not able to explain the fact, that an intimate relation subsists between puerperal fever and the swelled leg of lying-in women. Dr. Ferriar soon after maintained, without the slightest evidence, that there is a general inflammatory state of the absorbents in this disease.

Dr. Hull published an essay on phlegmasia dolens in 1800, in which he satisfactorily showed that it was impossible to account for the phenomenon of the disease on the supposition that the lymphatics were affected independently of a considerable primary affection of the sanguiferous system of the limb. He considered the proximate cause to consist in an inflammatory affection producing suddenly a considerable effusion of serum and coagulating lymph from the exhalants into the cellular membrane of the limb. All the textures, muscles, cellular membrane, lymphatics, nerves, glands, and blood-vessels, he supposed to become affected. (An Essay on Phlegmasia Dolens, by John Hull, M. D. Manchester, 1800.)

It is a remarkable circumstance in the history of crural phlebitis, that nearly a century and a half should have elapsed from the time when it was first clearly pointed out by Mauriceau, before an opportunity was presented of ascertaining by dissection the precise nature of the disease. There had indeed been opportunities to determine the accuracy of the different hypotheses which had been advanced, but these were neglected, and the seat of the disease and its commencement in the uterus were imperfectly understood until the writer of this article ascertained by dissection the true nature and origin of the complaint. (Pathological Researches on Inflammation of the Veins of the Uterus, Med. Chirurg. Trans. vol. xv. 1829.)

In January, 1823, M. Bouillaud related several cases and dissections in which the crural veins were obliterated in women who had suffered from a swelling of the lower extremities after delivery; and M. Bouillaud distinctly stated that he considered obstruction of the crural veins to be the cause, not only of the œdema of the lower extremities in lying-in women, but of many partial dropsies.

"Elizabeth Perfu, æt. 38, was received," he says, "into the Hospital Cochin two months and a half after her delivery. She had tuberculous phthisis, and the left lower extremity was infiltrated with serum. She died in three months, and on opening the body the veins of the affected extremity were found plugged up with a very old, red-coloured, easily broken-down fibrinous coagulum, which extended into the common iliac vein. The vena cava and the other veins were healthy, and contained more or less liquid blood."

Marguerite Colliere, æt. 30, was delivered by the forceps in the Maternité, about the end of January, 1822. She entered the Hospital Cochin on the 20th March following, having the left lower extremity greatly swollen and infiltrated with serum. She died on the seventh day after. An enormous abscess was found in the pelvis, which appeared to have commenced on the left side of the cavity before and within the psoas muscle. All the surrounding parts were extensively disorganized. The coats of the left iliac veins were thickened, and their interior layers were altered in structure, and converted into a lardaceous substance. The whole of the veins of the inferior extremity were plugged up with a solid friable clot.

M. Bouillaud observes that Chaussier and Meckel had both before related cases of swellings of the lower extremities in puerperal women, where the crural veins had been found inflamed and obstructed. (Archives de Médecine, tom. ii. Janvier, 1823.)

In May, 1823, the valuable essay of Dr. Davis on Phlegmasia dolens was read before the Medical and Chirurgical Society, subsequently published in the twelfth volume of the Transactions. Although the cases of M. Bouillaud were published four months before Dr. Davis's paper was read, it does not admit of dispute that Dr. Davis was the first who proved by dissection that phlegmasia dolens depended on inflammation of the iliac and femoral veins. So early as 1817 a fatal case occurred to him, which was examined by Mr. Lawrence, in which the iliac and femoral

veins were found inflamed and obstructed. Two other cases were recorded by Dr. Davis, and another by Mr. Oldknow, in all of which there were proofs of the previous existence of inflammation of the crural veins. (Med. and Chirurg. Trans. vol. xii. 1823.)

For six years after the publication of the cases of M. Bouillaud and Dr. Davis, pathologists remained in doubt whether these cases should be considered as examples of genuine phlegmasia dolens, or be viewed as essentially different diseases, and analogous in their nature to those formidable attacks of phlebitis which sometimes succeed to venesection and wounds. In opposition to the views of Dr. Davis, it was forcibly urged that if phlegmasia dolens depended on inflammation of veins, three out of four patients would die; whereas death does not take place in one case in an hundred where that disease is distinctly marked. Even that distinguished pathologist, Mr. Lawrence, who had examined the first fatal case which occurred to Dr. Davis, declared in the Medical and Chirurgical Society, as late as 1828, that he was fully convinced from what had subsequently fallen under his observation, that Dr. Davis's views were incorrect, and that phlegmasia dolens did not arise from inflammation of the iliac and femoral veins. Dr. Davis has communicated no additional information on the subject since 1823, and he is still of opinion that the inflammation commences in the common iliac, and not in the veins of the uterus, and that the disease is produced by the pressure of the gravid uterus during pregnancy.

In none of the cases of Dr. Davis does it appear that any attempt was made to trace the hypogastric veins to the uterus, though it is now certain, from what is known respecting the progressive changes witnessed in cases of phlebitis, that the alteration of structure which he has described must have originated in the veins of the uterus.

Thus, then, none of the writers who have been hitherto quoted have made any allusion to phlegmasia dolens commencing in the uterine veins; and even Mr. Velpeau, the latest continental author on the subject, has given it as his opinion that the affection of the veins is not the primitive disease, but is the consequence of the inflammation and suppuration of the articulations of the pelvis, with which he observed it to be frequently combined. The puriform fluid found within the veins he supposes to have been introduced into their cavity by absorption, and not to have been the effect of inflammation, nor the cause of those affections of the articulations, which is now known to be the case. How far this opinion was incorrect, we need not now point out.

It is due to Mr. Guthrie to mention, that in a paper on inflammation of veins after amputation, published in the Medical and Physical Journal for 1826, he suggested the importance of tracing the veins from the common iliac of the affected side down to the uterus, and expressed a suspicion that the disease would be found to originate in that organ.

All the authors who have treated of phlegmasia dolens describe it as commencing, in the great majority of cases, subsequent to the tenth day after parturition, with symptoms of uterine irritation and constitutional disturbance of a low typhoid character, and with pain and swelling in one extremity only. They have assigned various reasons for these remarkable peculiarities, in the period and mode of development of the disease, as pressure of the gravid uterus on the iliac veins during gestation, the change in the distribution of the blood from the sudden removal of this pressure, exposure of the extremity to cold, suppression of the lochia, deposits of milk in the limb; all of which, taken singly or combined, are insufficient to account for the phenomena; and the occurrence of the disease after menstruation, abortion, and the malignant affections of the uterus, proves that these causes are neither necessary nor sufficient for its production.

The numerous cases and dissections of which the writer of this article has published detailed histories in the Medical and Chirurgical Transactions, and in a recent work on the "Pathology and Treatment of some of the most important Diseases of Women," offer a more satisfactory, and, he trusts, a conclusive explanation of the phenomena. They demonstrate, that if inflammation be excited in the uterine branches of the hypogastric veins, it may continue to spread along these until it reaches the common external iliac and femoral veins, and by the morbid changes induced in them give rise to all the subsequent symptoms.

The two following cases are here introduced, not merely because they were the first in which crural phlebitis was distinctly traced into the uterine veins, but as they afford good examples of this affection in its most mild and most severe forms, and illustrate, better than any general description could do, the phenomena of the disease, and the alterations of structure produced by inflammation in the hypogastric and crural veins.

A patient of the British Lying-in Hospital, who had been suffering for some weeks before delivery (May 8, 1829) from the usual symptoms of tubercular phthisis, experienced, on the 4th June, a sense of soreness in the left groin, which gradually extended along the inner surface of the thigh to the ham, and from thence along the posterior surface of the leg to the foot. She stated that for two days before the occurrence of pain in the groin, she had felt great uneasiness in the region of the uterus, that this suddenly quitted the hypogastrium and passed into the groin, and that from thence it extended downward along the inner surface of the thigh to the leg. The limb became swollen twenty-four hours after the invasion of the disease.

The whole left inferior extremity is now affected with a hot, painful, colourless swelling, no where pitting on pressure, except over the foot. The thigh is fully double the size of the other, and any attempt to move the limb produces excruciating pain along the inner surface of the thigh; and the pain excited by pressure along the tract of the femoral vein is so acute, that the condition of the vessel cannot be ascertained. Several branches of the saphena major, above the knee, are distended and hard; pulse 120; respiration quick and laborious; tongue peculiarly red and glossy; diarrhœa continues. 10th. Pulmonary affection aggravated. The limb continues extremely painful, and is still more swollen. The groin is so tender that she

cannot bear the slightest pressure over it. The same is the case with the inner surface of the thigh. The branches of the saphena are still hard and painful. 11th. The femoral vein under Poupart's ligament can now be felt indurated and enlarged, and it is exquisitely painful when pressed; as is the inner surface of the thigh, the ham, and the calf of the leg. There is comparatively little tenderness along the outer surface of the limb. 17th. Diarrhœa, emaciation, colliquative sweats, and difficulty of respiration increasing. The left inferior extremity is still much swollen; but there is less pain in the groin and in the course of the femoral vessels. Died on the 24th.

Dissection. — Thorax. Adhesions between the pleuræ on both sides. Scarcely a portion of lung could be observed which did not contain tubercles in various stages of their growth. The right and left superior lobes contained several large tuberculous excavations. The vena cava and right common and external iliac veins were in a sound state. The *left common external* and *internal iliac* veins were all impervious, and had undergone various alterations of structure. The common iliac, at its termination, was reduced to a slender tube, about a line in diameter, which was lined with a bluish slate-coloured adventitious membrane. The remainder of the common and the external iliac veins were coated also with a dark-coloured membrane, and their centre filled with a brownish ochery-coloured tenacious substance, rather more consistent than the crassamentum of the blood.

The left hypogastric or internal iliac vein was in the same condition, but in some places reduced to a cord-like substance, and its cavity throughout completely obliterated. The branches of this vein, taking their origin in the uterus, and usually termed the uterine plexus, were found completely plugged up with firm, red coagula. From the commencement of the branches of this plexus of the hypogastric vein to the termination of this vein in the iliac, the whole had become thickened, contracted, and plugged up with coagula and adventitious membrane of a dark blue colour.

The same changes had taken place in the uterine plexus, and trunk of the right hypogastric vein, from the uterus to its unusual termination in the left common iliac vein. The coats of the left femoral vein were thickened, and closely adherent to the artery and surrounding cellular substance; its whole interior lined with an adventitious membrane, and distended with a reddish-coloured coagulum. The same morbid changes presented themselves in the deep and superficial branches as far as they were examined down the thigh.

A woman, aged forty, who had been delivered of twins a month before, and had nearly perished from flooding, and subsequently from an attack of uterine inflammation, was seized on the 27th August 1829, with a violent fit of cold shivering, followed by pyrexia and pain in the right iliac region and groin. In the course of the two following days, the pain increased in severity, and extended down the inner surface of the thigh towards the ham, and the whole leg and thigh became much swollen. 29th. The whole right inferior extremity affected with a general intumescence, and completely deprived of all power of motion. The temperature of the limb, particularly along the inner surface, much higher than that of the other; but the integuments retain their natural colour, and do not pit on pressure. The femoral vein for several inches under Poupart's ligament, is very distinctly felt enlarged, and is very painful when pressed. Out of the course of the crural vessels little uneasiness is produced by pressure. In the right side of the hypogastrium there is also great tenderness; pulse 120; tongue furred. She appears pale and depressed, and complains of deep-seated acute pain in the lower part of the back when she attempts to move. From this period until the 22d September, when she died, she suffered from repeated fits of shivering, which occasionally assumed a regular intermittent form; there was diarrhœa, with brown tongue; the glands in the right groin became much enlarged, and the left inferior extremity became affected in a manner similar to the right.

Dissection.—The veins presented nearly similar appearances to those observed in the preceding case. The divisions of the vena cava were in this instance both affected. On the left side the cavities of the iliac and femoral veins were filled with a dark purple coagulum, their coats being not much thicker than natural; whilst on the right side the coats of these veins were dense and ligamentous, and the cavities blocked up by adventitious membranes, or lymph of a dull yellow colour. The lower part of the vena cava, for the space of two inches, as well as the right common iliac, was obstructed by a tough membrane of lymph surrounding a soft semi-fluid yellowish matter. The right common, external, and internal iliac veins were imbedded in a mass of suppurating glands, the purulent fluid of which had escaped into the adjacent cellular membrane, and forced its way downwards in the course of the psoas muscle as low as Poupart's ligament. The right hypogastric vein was reduced to a small impervious cord, and its branches were distended with coagula of lymph of a bright red colour. The right femoral and its branches were in like manner impervious, their coats being greatly thickened, and their interior occupied by coagula. The cavities of the left common external iliac and hypogastric veins contained soft coagula, disposed in layers which adhered to the inner tunic of the vessel.

The trunk of the left hypogastric vein was contracted, its coats somewhat thickened, and its branches filled with worm-like coagula. The spermatic veins were healthy. The cellular membrane of both lower extremities was infiltrated with serum.

The *causes* of uterine and crural phlebitis have already been pointed out in the article Fever, Puerperal. Inflammation of veins, it was there observed, rarely takes place in any part of the body where it cannot be referred to a wound or to some specific cause externally applied to the coats of the vessels. In uterine phlebitis the inflammation cannot, it is true, be traced in all cases to the semi-lunar shaped orifices in the lining membrane of the uterus which communicate with the sinuses where the placenta had adhered; yet it scarcely admits of a doubt that the frequent oc-

currence of the disease arises from the orifices of these veins in the lining membrane of the uterus being left open after the separation of the placenta, by which a direct communication is established between the cavities of these veins and the atmospheric air, in a manner somewhat analogous to what takes place in amputation and other extensive wounds.

The veins which return the blood from the uterus and its appendages may be either wholly or in part inflamed; generally, however, the inflammation attacks the spermatic veins alone, and for the most part the one only on that side of the uterus to which the placenta has been attached: and it may confine itself to a small portion of the vessel, or extend throughout its whole course from the uterus to the vena cava. The same is the case with regard to the hypogastric veins, one only being generally affected. These veins are, however, rarely inflamed in comparison with the spermatic; and this would seem to depend on the latter veins being invariably connected with the placenta, to whatever part of the uterus it may happen to be attached.

In eight of the twenty-three cases of puerperal crural phlebitis which have come under the writer's immediate observation, the disease has commenced between the fourth and twelfth days after delivery, and in the remaining fifteen it appeared subsequent to the end of the second week after parturition. In most of the patients there was either an attack of uterine inflammation in the interval between delivery and the commencement of the swelling in the lower extremity, or there were certain symptoms present which are to be regarded as characteristic of venous inflammation, viz. rigors, headach, prostration of strength, a small rapid pulse, occasional paroxysms like those of ague, nausea, loaded tongue, and thirst.

The sense of pain at first experienced in the uterine region, has afterwards been chiefly felt along the brim of the pelvis, in the direction of the iliac veins, and has been succeeded by tension and swelling of the part. After an interval of one or more days, the painful tumefaction of the iliac and inguinal regions has extended along the course of the crural vessels, under Poupart's ligament, to the upper part of the thigh, and has descended from thence in the direction of the great blood-vessels to the ham. Pressure along the course of the iliac and femoral vessels has never failed to aggravate the pain, and in no other part of the limb has pressure produced much uneasiness. There has generally been a sensible fulness perceptible above Poupart's ligament, before any tenderness has been experienced along the course of the femoral vessels; and in every case at the commencement of the attack, we have been able to trace the femoral vein proceeding down the thigh like a hard cord, which rolled under the fingers.

A considerable swelling of the limb, commencing in the thigh and gradually descending to the ham, has generally taken place in the course of two or three days, and in some cases immediately after the pain has been experienced in the groin. In other cases the swelling has been first observed in the ham or calf of the leg, and has spread from these parts upward and downward until the whole extremity has become greatly enlarged. The integuments have then become tense, elastic, hot, and shining, and in most cases where the swelling has taken place rapidly there has been no pitting upon pressure or discolouration of the skin. In several well-marked cases, however, of crural phlebitis, at the invasion of the disease, the impression of the finger has remained in different parts of the limb, more particularly along the tibia; but as the intumescence has increased, the pitting upon pressure has disappeared, until the acute stage of the complaint has passed away. At the onset of the disease we have also observed, in several cases, a diffuse erythematous redness of the integuments along the inner part of the thigh and leg. In one individual only has suppuration of the glands taken place in the vicinity of the femoral vein but in several, by an extension of the inflammation, the inguinal glands have become indurated and enlarged. In some women the inflammation of the femoral vein has appeared to be suddenly arrested at the part where the trunk of the saphena enters it, and the inflammation has extended along the superficial veins to the leg and foot. The swelling and pain in these instances have been greatest along the inner surface of the thigh, in the course of the saphena veins. In most cases of crural phlebitis, not only the whole lower extremity, but the nates and vulva have been affected with a glossy, hot, colourless, and painful swelling, which has not retained the impression of the finger.

The power of moving or extending the leg has been completely lost after the disease has been fully formed, and the greatest degree of freedom from pain has been experienced by the patients in the horizontal posture, with the limb slightly flexed at the knee and hip joints. The severity of the pain and febrile symptoms has usually diminished in a few days after the occurrence of the swelling; but this has not invariably happened, and we have seen some individuals suffer from excruciating pain for many weeks, or through the whole period of the acute stage of the disease.

The duration of the acute local symptoms has been very various in different cases. In the greater number they have subsided in two or three weeks, and sometimes earlier, and the limb has been then left in a powerless and œdematous state. The swelling of the thigh has first disappeared, and the leg and foot have more slowly resumed their natural form. In one case, after the swelling had subsided several months, large clusters of dilated superficial veins were seen proceeding from the foot along the leg and thigh, to the trunk; and numerous veins as large as a finger were observed over the lower part of the abdominal parietes. In some women the extremity does not return to its natural state for many months or years, or even during life. In the summer of 1831, a lady was placed under our care for an affection of the left lower extremity, who, forty years before, had suffered from an attack of crural phlebitis in the same side. The left leg and thigh had remained larger and weaker than the other during the whole of this long period, and was liable to suffer severely from fatigue and slight changes in the atmosphere. This lady was attended in her confinement by a

celebrated London accoucheur, who was so strongly impressed with a belief of the truth of the doctrine of Puzos respecting milky deposits in crural phlebitis, that he ordered the infant to be kept night and day at the breasts, lest the milk should make its way into the thigh.

In four cases of this affection, after the acute symptoms had begun to subside, the same appearances were observed in the iliac and femoral veins of the opposite extremity, and the other thigh, the leg, and the foot became similarly affected. In two individuals only has the disease attacked the same extremity twice. In one woman an interval of twelve years elapsed between the first and second attack.

Dr. Hull has given the following description of the disease. (On Phlegmasia Dolens, p. 133, Manchester, 1800.) "It has in many instances attacked women who were recovering from puerperal fever, and in some cases has supervened, or succeeded to thoracic inflammation. It not uncommonly begins with coldness and rigors. These are succeeded by heat, thirst, and other symptoms of pyrexia; and then pain, stiffness, and other symptoms of topical inflammation supervene. Sometimes the local affection is from the first accompanied with, but is not preceded by febrile symptoms. Upon other occasions the topical affection is neither preceded by puerperal fever nor rigors, &c.; but soon after it has taken place, the pulse becomes more frequent, the heat of the body is increased, and the patient is affected with thirst, headach, &c. The pyrexia is very various in degree in different patients, and sometimes assumes an irregular remittent or intermittent type.

"The complaint generally takes place on one side only at first, and the part where it commences is various; but it most commonly begins in the lumbar, hypogastric, or inguinal region, on one side, or in the hip or top of the thigh, and corresponding labium pudendi. In this case the patient first perceives a sense of pain, weight, and stiffness in some of the above-mentioned parts, which are increased by every attempt to move the pelvis or lower limb. If the part be carefully examined, it generally is found rather fuller or hotter than natural, and tender to the touch, but not discoloured. The pain increases, always becomes very severe, and in some cases is of the most excruciating kind. It extends along the thigh, and when it has subsisted for some time, longer or shorter in different patients, the top of the thigh and the labium pudendi become greatly swelled, and the pain is then sometimes alleviated and accompanied with a greater sense of distension. The pain next extends down to the knee, and is generally the most severe on the inside and back of the thigh, in the direction of the internal cutaneous and crural nerves; when it has continued for some time, the whole of the thigh becomes swelled, and the pain is somewhat relieved; the pain then extends down the leg to the foot, and is commonly most severe in the direction of the posterior tibial nerve; after some time the parts last attacked begin to swell, and the pain abates in violence, but is still very considerable, especially on any attempt to move the limb. The extremity, being now swelled throughout its whole extent, appears perfectly or nearly uniform, and it is not perceptibly lessened by an horizontal position, like an œdematous limb. It is of the natural colour, or even whiter; is hotter than natural; excessively tense and exquisitely tender when touched; when pressed by the finger in different parts, it is found to be elastic, little if any impression remaining, and that only for a very short time."

After describing the manner in which the constitutional and local symptoms subside, Dr. Hull further observes, that "hitherto the disease has been described as affecting only one of the inferior extremities, and as terminating by resolution or the effusion of a fluid that is removed by the absorbents; but unfortunately it sometimes happens that after it abates in one limb, the other is attacked in a similar way. It also happens in some cases that the swelling is not terminated by resolution. For sometimes a suppuration takes place in one or both legs, and ulcers are formed which are difficult to heal. In a few cases a gangrene has supervened. In some instances the patient has been destroyed by the violence of the disease before either suppuration or gangrene has happened."

2. Crural Phlebitis in Women who are not in the puerperal state.—The cases which have been related in the work already referred to, prove that inflammation of the iliac and femoral veins is a disease not peculiar to women who have recently been delivered, but that it may also arise from suppressed menstruation, malignant ulceration of the os and cervix uteri, and other organic diseases of the uterine organs.

In a lady aged thirty-one, whose case has been recorded by Tommasini, the catamenia were suddenly suppressed from immersion of the body in cold water. Headach, fever, and swelling of one of the limbs took place, and in three months she was attacked with great anxiety, prostration of strength and spirits, and other signs of a severe disease. The pulse was frequent and irregular, and there was great anxiety in respiration; the blood drawn was buffy. Phlebitis of the inferior extremity manifested itself. The pulse became intermittent, the veins of the limb painful and turgid, and the skin covered with spots of a dark colour. The sense of oppression increased, and death took place about four months after the commencement of her illness. On dissection, the lungs were found inflamed. In the limb affected, the coats of the saphena, sural, popliteal, crural, and iliac veins were thickened, injected, and filled with coagula of blood which in some parts of the crural veins appeared to be changed into a fleshy substance. The coats of the iliac above the crural arch, to the bifurcation of the vena cava, were much thicker than the other veins, and more injected, without any manifest collection of purulent matter. The arterial system was healthy; the condition of the internal iliac and uterine veins has not been described, although there can be little doubt the effusion originated in the uterus. (*Tommasini*, Saggio di Pratiche Considerazioni fatte nella Clinica Medica di Bologna, p. 317.)

In four cases which have come under our observation, inflammation of the iliac and femoral

veins, giving rise to all the phenomena of phlegmasia dolens, has followed the sudden suppression of the catamenia from exposure to cold.

In the first there was great tenderness of the hypogastrium and left thigh, a rapid feeble pulse, delirium, brown tongue, vomiting, exquisite pain in several of the joints both of the upper and lower extremities, and abscesses formed in different parts of the body.

In the second case, which occurred in a young lady, the whole left inferior extremity was swollen, hot, and painful, but not discoloured. The femoral vein was felt under Poupart's ligament like a large hard cord, and pressure over it and along the course of the iliac veins of the same side produced great suffering. The affection presented the same characters as in puerperal crural phlebitis, and could be distinctly referred to the sudden suppression of the catamenia.

In another case, referable to exposure to cold, the disease occurred in both lower extremities.

In the article Œdema it is observed that in women suffering from amenorrhœa, œdema is one of the most common attendants. In these cases there is considerable tenderness in the course of the femoral veins, the most common site of this tenderness being just before the vein pierces the tendon of the triceps to pass into the ham, and probably depends on some inflammation of the vessel. (See Œdema.)

From cases which we have likewise related, it appears that uterine phlebitis sometimes follows abortion, and that it has taken place and proved fatal after the removal of a polypus of the uterus by ligature. Tenderness in the course of the venous trunks of the lower extremities, and œdema of the limbs, have also in several cases been traced to some external injury inflicted on the uterus.

The first case of crural phlebitis from malignant ulceration of the os uteri, came under our notice nearly four years ago, and for several weeks before death the patient experienced great tenderness in the course of the left femoral vein, with a tense swollen state of the limb. On opening the abdomen, the peritoneum covering the intestines and liver was found to be inflamed, with an effusion of purulent fluid into the abdominal cavity. The os cervix, and a great part of the body of the uterus, had been destroyed by phagedenic ulceration, and extensive openings had formed in the bladder and rectum. On the left side, between the remaining portion of the uterus and the pelvis, to the brim of which it firmly adhered, was a spongy cancerous mass, enclosing within it the branches and trunk of the hypogastric vein and artery, and a considerable portion of the common and external iliac veins. When cut into, it presented a spongy texture, and a thick whitish purulent fluid escaped, as if from numerous cells, but which were subsequently ascertained to be cavities of veins. A portion of the common and external iliac veins was lost in removing the parts from the body. What remained of the common iliac was reduced to a slender tube, which was partially coated on the inner surface with an adventitious membrane of a black colour.

The commencement of the external iliac was also contracted so as to be impervious, and lined with a dark-coloured false membrane. The common superficial and deep femoral veins were all plugged up with firm red coagula, the coats thickened, and the inner surface lined with adherent false membranes.

The cellular texture of the limb was loaded with serum; but in other respects it was healthy, as were the other tissues.

From these and similar cases which have since occurred to the writer, to Mr. Lawrence, (Med. Chir. Transact. vol. xvi. p. 59. 1830,) and to Dr. Blundell, it appears not only that inflammation of the veins of the uterus may be produced by malignant ulceration of the os and cervix uteri, but that this inflammation may extend along the internal to the common external iliac, and femoral veins, and thus give rise to all the phenomena of crural phlebitis, as observed in puerperal women.

[The view that phlegmasia dolens is a crural phlebitis, is now admitted by the generality of pathologists. (Churchill, *The Diseases of Females, including those of Pregnancy and Child-bed*, p 545, Amer. edit., by Dr. Huston, Philad. 1843; Raige Delorme, in *Dict. de Méd.*, xxiv. 250, Paris, 1841; and Hüter, in Encyclopäd. Wörterb. der Medicinisch. Wissenschaft. xxvii. 168, Berlin, 1842.)]

3. Phlegmasia Dolens in Men. — It has recently been ascertained that this disease, in the male sex, may commence either in the hemorrhoidal, vesical, or in some of the other branches of the internal iliac veins, in consequence of inflammation or organic changes of structure in one or more of the pelvic viscera. Crural phlebitis in men arises much more frequently, however, from inflammation being excited in the superficial veins of the leg, extending upward and involving the great venous trunks of the thigh and pelvis. External injuries, exposure to cold and moisture, and ulcers, are the most frequent causes of inflammation of the saphena veins. Amputation may also excite crural phlebitis, both in the veins of the same side and in those of the opposite extremity. Tumours, by pressing upon the vena cava and iliac veins, may also give rise to the disease.

The following observations will illustrate, though in a less perfect manner than might be desirable, this interesting part of the pathology of veins.

Mr. Lawrence examined the body of a man who died at St. Bartholomew's Hospital of cancer of the rectum, and he found the iliac veins inflamed and obstructed. The affection not having extended into the veins below Poupart's ligament, none of the usual symptoms of crural phlebitis manifested themselves.

In two cases of crural phlebitis, related by Mr. Holberton, the patients died of phthisis, with diarrhœa and ulcerations of the bowels. In the first case, the examination was imperfect, but in the second the writer traced the left hemorrhoidal veins close to the spots of ulceration in the mucous membrane of the rectum, and the coats of these vessels were unusually thickened, and exhibited other marks of previous inflammation. (Med. Chir. Transact. vol. xvi. part i. p. 70.)

The patient whose case has been recorded by Dr. Forbes, likewise died of phthisis, and suffered from diarrhœa. The internal iliac vein was not traced to the rectum, but Dr. Forbes has recently stated to us his belief that the mucous membrane

of the lower intestines was ulcerated. (Ibid. vol. viii. p. 293.)

Dr. Cheyne observes in his Report of the Whitworth Hospital, which contains an account of dysentery, that "it is worthy of remark that a swelling occurred in several of the patients, both males and females, resembling the phlegmasia dolens in all respects but in its connection with parturition."

Dr. Tweedie has related cases of fever which were followed by painful swellings of the lower extremities, which also in all essential circumstances resembled phlegmasia dolens; but as these patients recovered, the condition of the veins or the intestines was not ascertained. (Edin. Med. and Surg. Journal, vol. xxx.)

Drs. Graves and Stokes have subsequently related cases of painful swellings of the lower extremities after fever, which presented all the usual symptoms of phlegmasia dolens, and were considered by them to be identically the same diseases. In both, they remark, œdema occurred unattended by redness, but accompanied by increase of heat with great tenderness and pain, and followed for a considerable time by impaired motion of the limb. In both diseases the swelling and the other symptoms are frequently not confined to any one portion of the extremity, but extend uniformly over the leg and thigh. In both diseases, however, we have also often observed that the pain, heat, and swelling occupied particular parts of the limb, while the rest was comparatively free from disease. Thus, in some cases a portion of the thigh was extensively engaged while the leg and foot remained in the natural state, and after some days the diseased action seemed to change its place, and successively attacked the other portions of the limb, without, however, any precise order in the mode of succession. (Dublin Hospital Reports, vol. v. p. 29.)

In the spring of 1833 a case of chronic dysentery came under the observation of Dr. Macann, in which phlegmasia dolens took place a short time before death. On dissection, the common, external iliac, and femoral veins of the left side were found to be completely obstructed, and their coats extensively disorganized by inflammation. The writer is indebted to his friend Dr. Forbes for this valuable specimen of inflamed veins, which was presented to Dr. Forbes by Dr. Macann, previous to his departure for the West Indies. In the short notice of the case it is stated that both lower extremities were swollen. It has not been ascertained whether the condition of the lining membrane of the rectum was examined by Dr. Macann, or if he attempted to trace the hemorrhoidal veins to their commencement.

In Dr. Cheyne's cases of dysentery it is highly probable the disease commenced in the hemorrhoidal veins, and from the frequent occurrence of inflammation and ulceration of the intestines in continued fever, we are disposed to think the affection had the same origin in the cases of Drs. Tweedie, Graves, Stokes, and Macann.

A man, whose case is recorded by Cruveilhier, had a sound introduced into the bladder for retention of urine, occasioned by a swelling of the prostate. Pain was experienced soon after in one of the lower extremities, and the veins became painful and distended like hard cords. The patient died, and all the different degrees of phlebitis were observed in the veins of the limb. There can be little doubt, M. Cruveilhier observes, that inflammation of the prostatic or vesical veins had been induced by the introduction of the instrument in this case, but the examination not having been conducted with a view to ascertain this point, it was not positively determined.

More frequently, both in the male and female sex, the inflammation does not commence within the pelvis, but originates in the superficial veins of the limb, and gradually extends upwards to the large deep venous trunks.

Mr. C. Hutchison has related the history of an interesting case of phlegmasia dolens in a gentleman who received a blow on his right shin, immediately over a branch of the saphena vein, by a small piece of timber accidentally falling upon it. The accident was followed by considerable swelling and inflammation all over the limb; pain was felt in the direction of the upper third of the saphena before it actually dips to unite with the femoral vein. The whole leg and thigh soon became enlarged and inflamed, and many months after the acute symptoms had subsided, when we examined the limb with Mr. Hutchison, Sir Gilbert Blane, and Dr. Gairdiner, there could be no doubt that the saphena and femoral veins had become completely impervious from inflammation. (Med. and Chir. Transactions, vol. xv. 1829.)

Sir A. Cooper performed an operation for varix of the saphena vein, which was followed by inflammation of the coats of the vessel and all the symptoms of phlegmasia dolens.

The following fatal case of crural phlebitis, induced by exposure of the limbs to cold and moisture, has been recorded by Drs. Graves and Stokes. A young man, of a strong habit, was employed for two successive days in working in a ditch, and was consequently obliged to stand in water above his knees during that time. On the following day he became affected with lassitude, vertigo, and general weakness, and complained of severe pain in the right thigh. These symptoms continued for seven days, when he was admitted into the Meath Hospital. His countenance was anxious and depressed, the tongue furred; thirst, headach, urine scanty, turbid, and high-coloured; pulse ninety-six, skin mottled with petechiæ. In addition to these general symptoms, the respiration was laboured and unequal, with some cough; face very livid. But his chief complaint was a severe pain in the upper and anterior part of the right thigh, which was greatly aggravated by motion or pressure. He had also severe pain in the left hypochondrium.

At this time no swelling of the limb whatever could be detected; but in the course of two days the upper portion of the thigh became evidently swollen, the part being extremely tender, but not at all red. The pain of the side continued, and extensive bronchial and pneumonic inflammation was detected. General bleeding and very free leeching to the limb were employed. The blood was not inflammatory, and no relief was experienced by the patient. The swelling of the thigh increased; calomel and opium were freely exhibited, but without any effect. The typhoid symp-

toms increased, and the patient died on the fourth day after his admission.

On dissection, the right lower extremity was found to be tense and swollen in its superior portion, while the leg and foot were slightly anasarcous. The sac of the pericardium contained some sero-purulent fluid; and that portion covering the auricles and great vessels was vascular, and in many cases covered with coagulable lymph. Both lungs were in a state of extreme sanguineous congestion with commencing solidity in their posterior inferior portion, and general inflammation of the pleura. The bronchial mucous membrane was universally red, and the tubes filled with frothy mucus.

The vena cava contained a few portions of a substance of a granular appearance, friable, and of a yellowish colour. This did not adhere to the vessel, which otherwise appeared healthy. In the external iliac vein, however, just above Poupart's ligament, there was a large concretion of a similar nature nearly plugging up the vessel, and extending into some of the minute collateral branches. The lining membrane was red, and in one point adhered to the coagulum. No puriform matter could be detected. The femoral and popliteal arteries were healthy. The cellular tissue of the limb was œdematous. The condition of the saphena vein where it enters the femoral is not described, although the inflammation most probably originated in the superficial vessel.

On the 2d of February 1832, the body of an aged man was brought into the dissecting-room of Webb-street school. The whole left inferior extremity was much swollen, and a chronic ulcer was observed over the tibia. The coats of the saphena vein along the leg and thigh were found, on examination, to be much thickened, and plugged up with coagula of blood and lymph. The left common and external iliac and femoral vein to the ham were all completely obstructed with coagula of blood and lymph, and lined with adventitious membrane. The lower part of the vena cava, to the extent of three inches, was filled with a soft yellowish coagulum of lymph, which adhered to the inner coat of the vein. The coats of the principal arteries of the left lower extremity were ossified.

In April 1832 Sir Henry Halford read an account to the College of Physicians of crural phlebitis as observed in the late Earl of Liverpool. The attack commenced many years before; and it is highly probable, from a circumstance stated to us by Sir A. Cooper, that it was induced by exposure to a current of cold air, which passed through an open window and fell upon the lower extremities when but thinly clothed, his lordship being at a crowded levee. The left groin, thigh, and leg were affected; and in the acute stage of the complaint, leeches and the usual antiphlogistic remedies had been employed by Dr. Pemberton and Sir A. Cooper. Lord Liverpool subsequently died from an affection of the brain; and on examining the body, the left iliac, femoral, and saphena veins were found to have undergone changes of structure similar to those which have previously been described as occurring in puerperal crural phlebitis. Sir Henry Halford related two other cases of crural phlebitis in men. They were similar to the case of the Earl of Liverpool, and were succeeded by marked tendency to head affection. In none of the cases of crural phlebitis which have fallen under our observation, has any remarkable slowness of pulse or tendency to disease of the brain been observed. Even where the vena cava and both iliac and femoral veins have become completely impervious, the blood has been returned to the heart without difficulty, and no affection of the brain has taken place.

In a patient of the British Lying-in Hospital, who had suffered much from varicose veins in the latter months of gestation, inflammation of the saphena veins of both lower extremities came on two days after delivery with most severe constitutional symptoms. From the left knee to the ankle on its inner surface, the integuments were hot, and swollen, and tense, and in several places large patches of a dark red colour were observed over the superficial veins, which being laid open in two places, a considerable quantity of purulent fluid was discharged. Where the swelling and tension were least, the superficial veins could be felt distended like hard cords; as could also the saphena through its whole course upward from the ham to its junction with the femoral vein. In the course of this vein there was considerable swelling; and the integuments in this situation, as far as the middle of the thigh, were hot and of a dark red colour.

The symptoms which characterize venous inflammation in its most severe forms took place, and she sank on the fourteenth day after delivery. Dr. Sims assisted us in inspecting the body, when the following morbid appearances were observed. The left lower extremity was very much enlarged. The cellular and adipose membranes from Poupart's ligament, along the inner surface of the thigh and leg to the ankle, were indurated, vascular, and infiltrated with a red-coloured serous fluid. Several abscesses were observed in the cellular membrane immediately beneath the skin in the calf of the leg, and an extensive collection of pus had formed in the interstices of the gastrocnemii muscles. The branches of the saphena in this situation were converted into solid impervious cords; and the coats of this vein, from the knee to its junction with the femoral, were thickened and contracted, and in the lower part the cavity was nearly obliterated. The saphena vein was lined with an adventitious membrane of considerable thickness, which was easily separated from the inner coat. Its opening into the femoral vein, though reduced in size, was pervious; and the coats of the deep femoral vein, from this point to the ham, were thickened and contracted. The inner membrane was rugous, and of a deep red colour; but no deposit of lymph was observable, and its canal was pervious. The femoral vein above the termination of the saphena, and the whole of the external iliac, were thickened and slightly contracted in their dimensions, and lined with a thin coating of lymph. These vessels were pervious, and the common and internal iliac exhibited no sign of disease. The intestines were inflamed; and on the ascending colon there was a small part in the state of sphacelus. (Medical and Chirurgical Transactions, vol. xv.)

We have related other cases of inflammation of

the saphena veins, of less severity, occurring in puerperal women, where the swelling, heat, and tension were confined to the course of these vessels; and it is now clearly ascertained that the whole limb does not become affected when the iliac and femoral veins have remained pervious. The preceding and other cases likewise prove that the inflammation in crural phlebitis, when violent, is not limited to the coats of the veins, but may extend to the cellular membrane, glands, muscles, and other contiguous tissues.

In July, 1830, the author was indebted to the kindness of Dr. Ashburner for the opportunity of observing the progress of an interesting case of crural phlebitis in a female about the middle period of life, who had not been pregnant for several years. A small ulcer above the left internal malleolus gave rise to inflammation of the saphena and femoral, and probably of the iliac veins, and the whole limb became affected with a hot, shining intumescence.

Sir Charles Bell has informed us that he has observed upwards of twenty cases of painful swellings of the superior extremities in women afflicted with cancer of the mammæ. He has been accustomed to refer these swellings to obstruction of the lymphatics, or to compression of the veins by the induration and enlargement of the glands of the axilla. No opportunity has yet occurred to determine by dissection whether or not the painful swelling of the arms is to be attributed in such cases to inflammation and obstruction of the veins; but this has been rendered probable by the facts already related respecting the effects produced on the iliac veins by malignant ulcerations of the uterus. It is rendered still more probable by the following observation of Laennec: "that it is not uncommon to find the veins in the neighbourhood of a cancerous breast filled with pus, either pure or mixed with blood; sometimes fluid, at other times more or less inspissated, and occasionally of the degree of consistence of an atheromatous tumour." (*Translation*, 2d edit. p. 652.)

Treatment.—Puzos recommended repeated and copious venesection for the treatment of phlegmasia dolens; but in all the cases which we have witnessed, there has been so much feebleness of pulse and prostration of strength that we have not ventured to draw blood from the arm. There are cases, however, occasionally met with where the symptoms are immediately relieved by a general bleeding. An example of severe crural phlebitis after delivery recently occurred in the practice of Dr. Duffin, where the abstraction of twenty ounces of blood seemed at once to break the force of the attack. In a great proportion of cases venesection is not required, and we are to trust for the relief of the inflammation to the repeated application of leeches above and below Poupart's ligament, in the course of the crural veins. From two to three dozen of leeches should be applied immediately after the commencement of the disease, and the bleeding should be encouraged by warm fomentations, or by a bread and water poultice to the part. Should the relief of the local pain not be complete, it is requisite soon to reapply the leeches in numbers proportioned to the severity of the attack, and to repeat them a third or even fourth time, at no very distant intervals, should the disease not yield.

Some patients experience greatest relief from the use of warm cataplasms to the limb; others derive most advantage from the application of cold, or of a tepid, evaporating lotion.

The bowels are often much disordered in this disease; but the employment of strong acrid cathartics is always injurious. Repeated small doses of calomel and antimonial powder should be given with some mild purgative, not only with the view of correcting the disordered state of the bowels, but to subdue the local inflammation, and the great constitutional disturbance usually present. It is of importance, also, to administer saline and diaphoretic medicines, and to procure rest and relief from pain by anodynes, until the acute symptoms pass away: the diet should be the same as that usually allowed to patients who are labouring under inflammatory and febrile diseases. We have seen no advantage derived from the use of digitalis in any stage either of uterine or crural phlebitis. Dr. Sims has informed us that the painful swelling and tension of the limb, in a case of phlegmasia dolens, were strikingly relieved by puncturing the skin in different parts with a fine needle.

When the acute inflammatory symptoms have passed away, the limb remains in a weak, œdematous state, and great uneasiness is often experienced from congestion of blood in the veins. Until the collateral branches, which are to carry back the blood to the heart, become enlarged, it is impossible by any means we possess to afford complete relief. Much benefit may, however, be derived in this stage of the complaint from the occasional application of a few leeches to different parts of the limb, and by preserving it in the horizontal position. We have seen mischief produced by having recourse too early to remedies intended to promote the absorption of the fluid effused into the cellular membrane. Blisters, frictions, stimulant embrocations, and bandages to the limb, are only useful when the inflammation of the veins has wholly subsided, and other vessels have become so much enlarged as to carry on the circulation of the blood in the extremity without interruption.

We have not perceived any sensible benefit accrue from the use of mercurial ointment and iodine in crural phlebitis, and we consider the local abstraction of blood at the commencement of the attack to constitute by far the most important part of the treatment.

ROBERT LEE.

PHRENITIS. See BRAIN, INFLAMMATION OF THE.

PHTHISIS PULMONALIS. See TUBERCULAR PHTHISIS.

PITYRIASIS, from *πίτυρον*, *bran*, denotes a cutaneous affection in which irregular patches of the cuticle, varying much in size, appear covered with thin branny or minute powdery scales, which fall off and are soon succeeded by others. This disease is not contagious, and is seldom productive of inconvenience to the patient; it never terminates in crusts or excoriations, but, if neglected, it may alter its character and degenerate into porrigo. During health, the cuticle over the

whole body is constantly undergoing changes, peeling off in minute fragments, while a new and sound surface is formed below. Of this we have sufficient proof in the scales which are daily detached from the scalp by the hair-brush, and those which are always seen on drawing a black silk stocking off the leg. Now when this process of exfoliation is greatly increased on particular spots and patches of the skin, it constitutes the most simple form of pityriasis. There are several varieties of this affection.

1. *Pityriasis capitis.* (Dandriff of the head. Dartre furfuracée volante, *Alibert.*) This eruption is seen on the scalp and eyebrows of infants and sometimes of old men; on the temples and forehead it has a white mealy appearance; but on the occiput it consists of distinct flat scales, semi-transparent and of a light brownish colour. In children it is occasionally connected with imperfect nutrition, but most frequently originates from a mere want of cleanliness. In adults and the aged, dandriff of the head accompanies the falling off of the hair, which so often takes place during convalescence and under chronic disease. This form of eruption sometimes occurs also on the chin and other parts of the face, when they exhibit patches of a rough and mealy appearance; it is occasionally the result of indigestion, but more frequently of some local irritation, as acrid soap or a rough-edged razor.

Treatment. — This eruption, when on the scalp, in general yields readily to removal of the hair, washing of the affected parts with soap and water morning and evening, and anointing them afterwards with some mild cerate. All causes of local irritation must be removed, the general health attended to, and a plentiful supply of wholesome nourishment afforded, should that appear to have been deficient.

The other forms of pityriasis are more remarkable for the discoloration of the skin which attends them than for the mealy or branny desquamation of the cuticle; and hence, although Willan, Bateman, and other English writers, have considered them as species of pityriasis, Alibert, (Maladies de la Peau,) Rayer, (Maladies de la Peau,) and Biet, (Abrégé Pratique des Maladies de la Peau,) arrange them among the *ephelides*, or *tan-spots*. We prefer adhering to the arrangement of our countrymen, because we have always observed some exfoliation of the cuticle in these forms of pityriasis, at least during the height of their course; and because they differ from true ephelis in appearing especially on those parts of the body which are not exposed to the sun's rays. Three varieties have been distinguished by the names of *versicolor*, *rubra*, and *nigra*.

2. *Pityriasis versicolor.* (Chequered dandriff. Ephelides hepatiques; chloasma pseudo-porrigo; maculæ hepaticæ; leberflechte.) This is characterized by yellowish or light brown spots, and sometimes large patches of the most irregular outline, branching into the healthy coloured surface, or enclosing portions of it; not in the least elevated, and usually covered thinly by fine powdery scales. The colour varies in intensity according to the greater or less vascular turgescence of the skin, and when this is much excited, verges into the reddish tint of the succeeding variety. The most frequent seats of this eruption are the front of the chest and upper part of the belly; it appears also on the neck and back, and sometimes on the shoulders and arms. It is seldom productive of any discomfort, except under particular circumstances of excitement, when it is accompanied by itchiness of the skin on the patient becoming warm in bed; and should the stomach be disordered, this occasionally proves very troublesome. But the great source of uneasiness is more commonly in the mind, from the fears of the patient, who sees in this affection what he imagines to be the copper-coloured blotches of a confirmed venereal infection. Many times have we been consulted by persons affected with the light brown and red varieties of pityriasis under this impression, and not a few of them had been subjected to prolonged courses of mercury and sarsaparilla,—we need not add without benefit. The difference between pityriasis and syphilitic eruptions is abundantly well marked, the latter being of a darker and more coppery hue, distinctly elevated above the surface, and leading ultimately to the formation of crusts and ulcerations—appearances which are not observed in any form of pityriasis.

A diversity of opinion exists respecting the anatomical seat of pityriasis versicolor; Dr. Willan (On Cutaneous Diseases, vol. i. p. 194,) states that the rete mucosum or cutis is always affected in this disease, the brown stain being still perceptible after the cuticle has been removed; while Dr. Bateman, (Synopsis, p. 47,) on the other hand, asserts that in some cases he has seen the discoloured cuticle peel off at intervals in a thickened state, leaving a new cuticle underneath of a red hue. But to this latter statement it may be fairly replied, that when the cuticle becomes thickened and thus peels off, the disease has lost the genuine character of pityriasis versiclor. With a view to decide the question, we applied a blister to a portion of skin affected with this disease. After the cuticle was wholly removed, the mottling still remained; but the patches, instead of being tawny, were now changed to a deeper red than the rest of the excoriated surface; thus proving to our satisfaction that the anatomical seat of pityriasis versicolor lies beneath the cuticle.

It is rarely in our power to trace the occurrence of this cutaneous affection to any satisfactory cause, we have sometimes seen it connected with a feeble digestion and indifferent health; but on other occasions nothing of this kind could be observed. An opinion held by some, that it is dependent on disease of the liver, probably originating in the name *maculæ hepaticæ*, is certainly quite groundless. Bateman has observed this eruption in a severe form to follow the free use of spirits while fasting, and exposed in an open boat; and Dr. Willan speaks of various sources of irritation of the stomach and skin as possible causes of this disease, such as acid fruits, mushrooms, sudden alterations of temperature, violent exercise with flannel next the skin; but the whole of these are more likely to give rise to urticaria than to pityriasis.

Treatment.—It must be acknowledged that we have not much power over this disease by in-

ternal remedies; and after the patient has been satisfied as to its innocence and the absence of of all syphilitic taint, he often ceases to think of it, and allows time, if it will, to work a cure. Should the disease seem to have originated from any irritation either of the cutaneous surface or of the alimentary cavities, its cause must, if possible, be removed without delay: when the digestion is impaired, light tonics are to be used, as infusion of calumba with sulphuric acid, or small doses of sulphate of quinia; the bowels are to be regulated, and a milk and nourishing diet enjoined, with abstinence from spirituous liquors, and a very guarded use of wine and ale, if any be allowed. When itching exists, a spirit lotion with borax or alum, or acetate of lead or zinc, will be found useful; or, what rarely fails to give relief, a lotion with hydrocyanic acid. The vapour bath at a moderate temperature will serve to equalize the cutaneous circulation, and soften the branny spots. In our hands nothing has proved so effectual in restoring the natural colour and functions of the parts as a lotion of chloride of lime or soda, varying in strength according to circumstances. The success which has attended this application has exceeded our expectations; but whether its effects are to be regarded as the result merely of a stimulus, or of its bleaching property, admits of question.

[Iodide of sulphur makes an excellent ointment in this as in various other chronic diseases.]

3. *Pityriasis rubra* (red dandriff.) This differs from the preceding species chiefly in the redness of its colour, and the greater excitement of the surface which attends it. It is more uniformly accompanied by heat, itching, and general languor and restlessness, and may be considered as remotely allied to psoriasis diffusa, although altogether free from elevation above the surface, and vastly more mild in all its symptoms. On its decline, it leaves sallow faded stains marking the parts which were affected. The anatomical seat of pityriasis rubra is certainly deeper than the cuticle; its red colour evidently depending on the injected state of the vascular tissue lying beneath.

Treatment.—We have never in any case of red dandriff found the irritation such as to require the abstraction of blood; but in every instance the bowels should be opened by mild purgatives, and those which correct acidity. A soothing or slightly astringent lotion, such as those already described, ought to be applied to the affected parts, and any cause of cutaneous irritation immediately removed.

Dr. Bateman has recommended a diaphoretic plan of treatment,—antimonials, with decoction of the woods, and the warm sea-water bath; and he adds that he has found benefit from small doses of the *tinct. veratri.*

4. *Pityriasis nigra* (black dandriff; éphelide scorbutique). This is an exceedingly rare disease; so much so that Dr. Willan had not seen it at the time of his publication, and Dr. Bateman does not appear to have ever met with it. Alibert has described it under the name quoted above, and figured it as it affects the hands (plate 27 bis.) The cases seen by Dr. Willan occurred in children born in India, and brought to this country. The disease commenced in a partially papulated state of skin, and terminated in a black discoloration, with slight furfuraceous exfoliations: it sometimes affected half a limb, sometimes the fingers and toes. (*Bateman*, Synopsis, p. 49.) In allusion to the foreign origin of this species of pityriasis, we may mention a curious dusky mottling of the skin, which is seen in the children of mulatto women by European fathers, when they approach, as they sometimes do, to the fair complexion of the European. It seems as if patches of the dark hue of the mother shone through the pure skin of the father; and it is chiefly perceptible when they are heated with exercise, or the skin otherwise increased in vascularity.

Some years ago, we had the good fortune to see a case of pityriasis nigra. The patient was an unmarried female, aged forty-five, a native of Scotland, her parents Scotch; and she had never travelled to any distance beyond the precincts of her native city. The skin of her arms, legs, bosom, and neck, but especially the last, was of a dark tint like that of a mulatto, but varying in different parts in depth of hue; and scattered over the dusky surface were many white spots, from which crusts appeared to have separated; and on other parts some crusts appeared still adhering. Both the white spots and the mulatto-coloured surface were slightly scaly. With this disease was combined an eruption of scabies affecting severely the hands, from the itching of which she suffered great annoyance. The disease had existed for some months; and at the time when it commenced she was reduced to a state of great misery and destitution. By the employment of sulphur frictions, the warm bath, and a plentiful supply of nourishing food, the natural colour of the skin was nearly restored after the lapse of some weeks; but we are ignorant whether a complete cure was in the end effected. This case confirms the remark of Dr. Bateman, that the disease is the result of misery and filth, but not his opinion that both the disease and its cause are wholly unknown in this country. (Synopsis, p. 49, note.)

Treatment.—Our first object in pityriasis nigra is to clear out the bowels by mild purgatives, and thoroughly purify the surface of the body with soap and water. A course of tonic aperients, with the regular use of the warm water or vapour bath, should then be prescribed, while the patient is put upon a moderate allowance of nourishing food. As his appetite and strength improve, the quantity of food is to be increased, and the warm bath exchanged for sulphur fumigations; or if the disease prove obstinate, recourse ought to be had to the cautious employment of the arsenical liquor, and the external use of the chloride of lime or soda, as in pityriasis versicolor.

W. Cumin.

PLAGUE, from πληγὴ, Gr. *plaga*, Lat. a *blow* or *wound;* th. πήσσω, *to strike.*—This is the name of a well-known and extremely fatal disease, which is endemic in Egypt and certain other countries bordering on the Levant, and has made frequent and destructive irruptions into Europe. The malady thus designated is called *pestis* and *pestilentia* by the Latin writers, λοιμὸς by the Greeks, *la peste* by the French, *pestilenza* by the Italians, and *pest* by the Germans, which last name is not unfrequently bestowed upon it by

ourselves. It is a curious fact that these words have each in their respective languages a signification distinct from the primary one, and expressive of various kinds of moral and physical evil, the malignancy of the disease in all situations being thus evinced by its suggesting the same analogy to people differing widely in physical constitution and mental habitudes.

The words plague, pest, and pestilential, and their corresponding terms in different tongues, have frequently, even when applied to diseases, a sense considerably vague. The disease we are about to treat of has always been comprised in these terms, but other maladies have been similarly designated, with which, probably, it had no quality in common excepting that of being extremely diffusible and fatal; and hence by *morbi pestilentiales* we are not always to understand a form of plague in a strict sense of the word. This want of precision of language is very conspicuous in Hippocrates and his commentator Galen, (Galeni Commentar. in lib. i. Epidemic. in lib. iii. cap. xx.; et in Aphor. lib. iv. &c.) whose idea of a pestilential disease appears to have corresponded very nearly with that which we express by the term epidemic; and a similar want of accuracy is perceptible in the writings of the Arabians, from whom we might for obvious reasons have expected the greatest precision.

The subject was so much obscured by the vague application of terms, that even at so late a period as 1775 the Faculty of Medicine of Paris proposed the following queries as the subject of a prize essay: "*If plague be a distinct disease*, what is its character? and what are the means of treating and preventing it?"—queries which were thought to have been successfully solved by M. Pâris of Arles. We need scarcely observe, what is now universally admitted, that the characters of plague are as distinctive as those of small-pox, measles, scarlatina, or any other disorder.

This disease is endemic in Egypt, and very often exists in adjacent territories; but the former country is unquestionably the great source whence it extends its ravages into surrounding districts; and a very learned and ingenious writer is of opinion that there only is it ever engendered, and that in other regions it is always an alien. (*Foderé*, Dictionnaire des Sciences Médicales, v. 41. p. 87.) In Egypt it is said to arise every autumn, and to prevail till the beginning of June of the succeeding year: its ravages then cease, and its contagion is extinguished or remains in abeyance during summer, to be again called into existence or activity in the autumn. The vernal equinox is the period of the greatest fatality of the disease. About this time, we learn, southerly winds blow with great violence. They last ordinarily three or four hours, and are frequently renewed daily for fifty successive days. They are very warm, passing over the burning deserts which border Egypt on the south, and they are, moreover, loaded with putrid emanations exhaled from the animal and vegetable substances which are decomposed in the lakes formed by the retiring of the waters of the Nile, or in the cemeteries which its inundation has reached. At this sickly season, diseases of all kinds assume a malignant character: it was at this season, that after the great inundation of 1801, the plague committed the greatest ravages among the inhabitants of Cairo, and Upper Egypt. In June the wind blows from the north, and being cooled in traversing the Mediterranean, renders that season the most refreshing and salubrious of the year, during which no sickness manifests itself. (*Baron Larrey*, Description d'Egypte, ou Recueil d'Observations et de Recherches, &c. publié par ordre du Gouvernement, Paris, 1821.)

It was to be expected that a disease eminently contagious should be occasionally diffused through countries having incessant intercourse with the land of its origin; and we find it repeatedly visiting the people, paying allegiance more or less direct to the Ottoman Porte, and not unfrequently ravaging Constantinople. Formerly it penetrated into more northern climes. Previously to the year 1665 it usually invaded England, as Sydenham informs us, at intervals of from thirty to forty years; but since the cessation of the celebrated epidemic of that year, which destroyed eight thousand inhabitants of London in the course of one week, though two-thirds of the population had previously fled from the city, it has not been seen in Britain. In other European countries it has much more recently manifested itself. Marseilles, which had previously suffered twenty severe visitations in the course of seventeen centuries, was ravaged by it in 1720; Moscow suffered a severe infliction in 1771 and 1772; and within the present century it prevailed at Noja in the Neapolitan dominions, in 1815 and 1816; it appeared in the Lazaretto of Venice in 1818, and at Gressemberg in Silesia in 1819. But with these exceptions it has been for a century generally confined to Africa, the land of its origin, and to those portions of Asia and Europe which own the Ottoman sway.

[A concise history of the disease is given by Vetter, in Art. *Pestis*, in Encyclop. Wörterb. der Medicinisch. Wissensch. xxvi. p. 625: Berlin, 1841.]

Symptoms. — The following definition will suffice to convey a general idea of plague, although, as is usually the case with nosological definitions, it does not comprise certain cases sometimes observed, which form exceptions to the ordinary character of plague:—an exanthematous disease, the eruption consisting of buboes, carbuncles, and pustules, white, livid, or black, distributed in various parts of the body, and generally attended with malignant and very fatal fever.

Various divisions have been proposed by systematic writers; but there is every reason to think that there is no difference existing between cases of the disease which can be regarded as specific, all the varieties being found intermingled in the same epidemic. Plague possesses two prominent characteristics—fever and eruption, both of which are found in fully formed cases; but examples of the existence of one of these symptoms without the other are not of unfrequent occurrence. The cases in which the eruption is wanting constitute the most rapidly fatal type of the disease; whilst, on the other hand, bubo occurring without constitutional disturbance is the slightest form in which this disorder, usually so fatal, can exist. Between these extremes there are various shades of intensity discernible, which, as well as the most

severe and the mildest type, we shall endeavour to depict.

The following sketch of the most rapid and intense form will remind the reader of malignant typhus, and of cases of the ordinary exanthemata, in which the system is so entirely overwhelmed that the eruption fails to appear, or displays itself but faintly. The patients are sometimes attacked suddenly with a loss of strength, a sense of confusion or weight in the head, occasional giddiness, oppression about the præcordia, and extreme dejection of spirits. They are inclined to be silent, and show great anxiety in their aspect, but make little or no complaint, and, either having no febrile symptoms or such as are very obscure, are considered by the persons about them as indisposed in a slight degree. Death takes place in such cases sometimes within twenty-four hours, or occasionally on the second or third day.—Neither buboes nor carbuncles appear, and it is rare to find suspicious marks of infection on the dead bodies. (*Russell*, History of the Plague at Aleppo in 1760, 1761, and 1762, p. 96.)

Others, who are at first attacked in the same manner as the foregoing, become in a few hours more manifestly disordered. Their eyes become muddy, the surface of the body cold; they grow drowsy and lethargic, and complain of pain at the heart. As the distemper advances, they often lose the power of speech; the skin seldom recovers its warmth, or, if it does, there is a mere irregular flushing, which soon gives place to cold and clammy sweats. The pulse sometimes remains nearly in its natural state, but is generally low and quick. Patients are by turns delirious, confused, and sensible, but the comatose disposition is the most prevalent. Towards the close there is incessant inquietude. Buboes rarely appear, and in those only who survive the third day; petechiæ, vibices, or broad, livid, roundish spots occur sometimes, but are not common, and the two latter are seldom visible till after death. All the cases of this description which fell under Dr. Russell's observation were fatal, the patients generally dying on the second or third day, a very few living till the fifth. (Ibid. p. 97.)

This intense form of the disease is most frequently observed at the commencement of an epidemic of plague, when it generally possesses the greatest malignancy. At a later period the following more mild but still dangerous variety is that which is most commonly met with.

The disease commences with coldness sometimes amounting to shivering, which is speedily followed by fever, accompanied occasionally with vomiting, and uniformly with giddiness and pain of the head; but rarely at first with delirium, and scarcely ever with a comatose disposition. The fever increases during the latter part of the day and the following night, but there is a perceptible remission, though by no means a cessation, of fever the following morning. In this form of disease, buboes and carbuncles generally make their appearance the first day, and it is not unusual to see successive eruptions of them appear throughout the disorder.

As the second day advances, there is again an exacerbation of fever; some of the sick are harassed by vomiting; there is distressing headach; the tumours are painful; there is confusion of thought, occasionally a slight disposition to coma; and the muddy eye, so characteristic of the disease,—in which Dr. Russell says muddiness and lustre are so strangely blended together—manifests itself. The skin is hot, the pulse frequent, the tongue dry; the patient is anxious, restless, and complains of pain or oppression about the heart. As night approaches, the feverish symptoms are aggravated; the heat is more intense; the pulse less full, but very quick; the jactitation is great, the eye very muddy, and the patient is disposed to incoherent raving or to stupor. Sweat breaking out early in the morning of the third day always brings a mitigation of the symptoms, and sometimes proves completely critical, but more commonly produces only a remission so favourable as to encourage the expectation of a more perfect crisis on the fifth. But where the patient neither sweats nor experiences a sensible remission on the third day, as is sometimes found to occur without perspiration, danger is always to be apprehended. During these remissions, it should be observed, the pulse becomes slower, softer, and more full, especially after perspiration; and though the eyes still remain muddy, the anxiety and disquietude abate, the intellectual faculties are clearer, and the patient finds himself in every way better.

There are again exacerbations on the third and on the fourth day. A remission takes place on the morning of the latter of these days, preceded by perspirations, but rarely so profuse as that which takes place on the third. The exacerbation of the fourth day is more severe, especially towards night, than that of the second and third, and continues intense till perspiration appearing on the morning of the fifth, and increasing to a profuse sweat of various duration, leaves the patient faint and languid, but in every other respect manifestly relieved. After this day the subsequent exacerbations become slighter and slighter, and the buboes generally advancing favourably to suppuration, little or no fever remains after the beginning of the second week, excepting symptomatic heats occasioned by the eruptions. But where the sweat on the fifth day proves imperfectly critical, milder exacerbations, which usually decline with gentle perspirations, continue to recur till the seventh day, when a second profuse sweat places the patient beyond all danger.

The formidable symptoms which generally occur on the second day in this form of the disease, sometimes do not take place till the third or fourth, and hence it sometimes happens that those who for some days seem to be slightly affected suffer a tedious illness or die contrary to expectation, while more alarming attacks terminate favourably. In the latter case the event remains doubtful till the fifth day; in the former till the end of the week. At these periods a conjecture as to the result may be made with tolerable success; though cases sometimes occur in which matters remain in suspense some days longer.

A much more severe and fatal form of plague, constituting the second class of Dr. Russell, begins generally with slight shivering or sense of cold, which is soon succeeded by fever, accompanied with giddiness, headach, vomiting, and sometimes purging. The fever increasing towards

night, the face becomes flushed, the eyes glisten, and the patient either becomes delirious, or drowsy and comatose. The pulse in this stage usually continues full and strong, and though the tongue is not dry, the thirst is excessive; but the stomach retains little of the liquid taken, and the patient, harassed by the vomiting and other symptoms, passes a very unquiet night. There is an abatement of the symptoms on the succeeding morning; but the pulse is frequent and more or less full, the skin is hot and dry, and the patient dejected. As the day advances, there is an exacerbation, the accession of which is accelerated by vomiting and especially by diarrhœa, which frequently supervenes at this time. The symptoms during this exacerbation are muddy eyes and a peculiar confused expression of countenance, quick pulse, sometimes low and fluttering, but rarely intermitting; a whitish, but rarely a parched tongue; the external heat moderately feverish, or occasionally intense in irregular flushings; pain at the heart or oppression about the præcordia; burning pain at the pit of the stomach and incessant inquietude. The more or less rapid progress of these symptoms denotes more or less danger; but when to these are joined a faltering in the tongue or loss of speech, while the surface of the body, losing its natural or feverish heat, becomes cold and damp with clammy sweats, death is inevitable, though perhaps the fatal moment may still be at some distance. In certain cases, especially where vomiting has been severe, and where diarrhœa or hemorrhage adds to the debility, the third day proves fatal; but the disease is more commonly protracted two or three days longer, advancing so far regularly to its termination, that each subsequent night proves worse than the preceding, and in the day the remissions are so transient and obscure as to leave no room for hope.

Few of the sick recover from this form of plague, whether the disease be left to itself or treated methodically; neither does the result appear to be materially influenced by the course of the buboes. They generally appear on the second day, sometimes on the third, and occasionally later. Suppuration does not take place, and the tumours, advancing or not towards this state, have no visible effect in hastening or retarding the termination of the disease. Carbuncles, as well as petechiæ and vibices, are occasionally met with. (*Russell*, p. 101.)

In the cases of which the eruption constitutes the principal feature, either buboes or carbuncles form, and frequently both occur in the same subjects. The patients are so little indisposed as to be able to walk about the streets or labour at their accustomed avocations, unless prevented by the inflammation of inguinal buboes. Even in more intense forms of the disease, the prostration of strength is in some cases slight; for in the expedition into Syria of the French army of Egypt, several soldiers affected with plague were able to march during a considerable length of time, (*Foderé*, Dictionnaire des Sciences Médicales, vol. xli. p. 77,) and Diemerbroeck relates many examples of which he was an eye-witness, of infected persons walking within a few hours of their death. (De Peste, obs. xxxvi. et liv.)

The pestilential bubo is a swelling of the glands of the groins, the axillæ, the neck, or of the parotid itself; though tumours in this last situation are sometimes named distinctively parotids. Buboes are at first small and deeply seated; they are more or less painful, but never entirely indolent, and they advance towards the surface, and in some cases to suppuration, with various degrees of rapidity. They terminate either in resolution, suppuration, or gangrene; but this last termination is rare, though examples of it are recorded by authors, (*Diemerbroeck*, part i. p. 431); and it is remarked that it rarely takes place in the cellular tissue, but merely in the gland itself, and hence that it can be ascertained only by dissection. (*Russell*, p. 115.) It is considered in all cases a fatal termination. There is a general opinion that the suppuration of buboes, if not essential to the safety of the patient, is in the highest degree conducive to his recovery; but it having been repeatedly observed that buboes never begin to inflame externally, or to show signs of approaching suppuration till the fever is manifestly on the decline, and restoration to health having taken place in innumerable instances though buboes did not undergo this process, there is every reason to think that too much importance has been attached to it, and that it is at most rather a sign than a cause of recovery. Buboes are rarely solitary, two, three, or four existing in the same subject; and this circumstance, their complication with carbuncle and other forms of eruption, and the antecedent and concomitant symptoms which generally exist, will secure us from confounding them with syphilitic swellings. It should be remarked, moreover, that pestilential bubo in the groin generally affects the glands in the vicinity of the crural vessels, though it sometimes appears in the situation of the ordinary venereal tumour.

Besides buboes situated in glandular parts, tumours to which the same name has been given are found in various situations, as on the head, the nape of the neck, the shoulders, the thorax, the vicinity of the umbilicus; in short, they may appear in almost any part of the body or limbs.* During six or eight days they are small hard bodies which do not involve the superjacent skin; but subsequently to this period they become protuberant, and the integument is inflamed. They sometimes disperse, but more frequently suppurate, though more slowly than the glandular bubo. They are numerous, from five to nine generally existing in one subject. Dr. Russell calls them spurious buboes.

Carbuncles may form in any part of the body, and they are not unfrequently observed in the integuments covering buboes. Various forms of them are described, but it is probable that varieties have been multiplied by observers depicting the same species in different stages of its progress. They commence generally in a pustular form, but occasionally like a vesication of the size of a horse-bean, filled with a dusky-yellow or blackish fluid. In the more advanced stage they are hard and very painful, speedily becoming gangrenous, and forming eschars, which tend to spread and

* *Russell*, p. 118. *Zacutus Lusitanus*, apud Diemerbroeck, p. 66. Goodwin's Historical Account, p. 49, and *Baron Larrey*, in the Dictionnaire des Sciences Médicales, tom. xli. p. 77.

rapidly destroy the skin, and sometimes muscular and tendinous parts. They occasionally exist in considerable numbers on the same patient. When recovery is approaching, suppuration takes place round the edges of the eschar, which, separating, leaves an ulcer of greater or less depth, discharging abundantly for some time and then gradually healing; but in fatal cases the eschar remains dry, with little appearance of being cast off.

There are other cutaneous affections observed in plague: of this kind are petechiæ, at first of a pale or purplish red, and subsequently livid; a certain marbled appearance of the skin, evanescent till towards the close of the disease, the variegating colours being of a pale faint blue or darkish red, and an erysipelatous efflorescence remaining visible for a short time. Narrow streaks of a reddish purple or livid colour are sometimes observed; and when they affect the face, they give a frightful appearance to the countenance, producing such an alteration of features, and so disguising the patient, that he can scarcely be recognised by his acquaintances. Vibices, or weals, and large blue or purple spots, the maculæ nigræ of authors, occur in the more depending parts of the body sometimes shortly before death, but they are more frequently not discoverable till after this event, and in both cases probably result from the infiltration into the subcutaneous cellular membrane of the blood attenuated by the disease.

Morbid Anatomy.—In a disease considered highly contagious, a deficiency of information on this head is to be expected, and we find that writers on plague are more copious on any branch of the subject than this. Some authors have, however, endeavoured to illustrate the nature of the disease by dissection, but it must be acknowledged without much success. Deidier made many dissections of persons dead of plague at Marscilles in 1720; but the only material result of his labours was the discovery that the gall-bladder was extremely loaded with black or greenish bile. (Dissertation sur la Contagion de la Peste, Montpellier, 1725.) Another observer of the same epidemic informs us that in some bodies every thing was found in a natural state, and in others that nothing was discovered but slight traces of inflammation of the intestines, which, the writer remarks, were certainly produced in the last moments of the disease. (Relation Historique de la Peste de Marscille, p. 447, 448.) Savaresi, in his Topography of Damietta, relates that in three cases the only morbid appearances were the lining of the intestinal canal and the stomach being covered with a yellowish mucus, and a general hardness of the conglobate glands. (Histoire Médicale de l'Armé d'Orient, p. 89.) Certain individuals have expected to derive information regarding the nature of the disease from the condition of the blood; but the humoral pathology does not appear to have furnished results more satisfactory and uniform than the inspection of the solids; the blood having been found in various states, namely, of a natural consistence and appearance, unduly liquid, and inflammatory or sizy. (Relation Historique, p. 447.) In conclusion, we are compelled to acknowledge that plague is one of the numerous diseases in which the changes during life leave no determinate trace after death to explain their nature or the cause of their fatal issue.

[Of late years, extensive opportunities have existed for noting the morbid appearances in plague. As the disease generally occurs in Mahomedan countries, and as a strong objection exists in them to *post-mortem* examinations, difficulties were at one time thrown in the way of the pathologist: and besides, as already remarked, the ideas in regard to the contagious nature of the disease, have prevented physicians from availing themselves as extensively as they might have done, of the numerous cases that presented themselves to their notice. In recent periods, the abhorrence entertained for dissections has diminished; and the notions of the contagious nature of plague have not been credited by many physicians; hence, necroscopie examinations have been by no means unfrequent; so that we have now numerous records of personal observation, not only of European physicians, but by a Mahomedan, and native of Egypt,—Clot Bey. (Bulard, *De la Peste Orientale*, &c. Paris, 1839. Clot-Bey, *De la Peste Observé en Egypte*, Paris, 1840; and E. Littre, Art. *Peste*, in *Dict. de Méd.* xxiv. 44: Paris, 1841.]

Nature of Plague.—This dreadful disease, like others of the febrile class to which it belongs, evidently results from the introduction into the system of a morbific poison; but much obscurity prevails with respect to the part of the frame which it first affects, and many of the pathological changes which it ultimately produces. The external inflammations and the fever are the only parts of the disease of which we have distinct knowledge. It has already been stated that examples occasionally occur of the absence of one or the other of these phenomena, the imperfection of medical definitions being exemplified by plague as by many other diseases. This imperfection, resulting from the variable phenomena with which the physician is conversant, so markedly contrasted with the uniformity presented by nature to the philosopher, or which in his experiments he can form for himself, does not invalidate the substantial accuracy of the definition, which comprehends an immense majority of cases, and excludes only what may be justly considered as the exceptions to the rule. Many persons have been disposed to look beyond the manifest symptoms of the disease to the interior changes of which these are only the signs or the effects; but it is to be feared that there has been more of speculation than of cautious induction from facts in the opinions these individuals have published to the world; or at least they have made a portion only, and this the smaller portion of cases of plague, the representatives of the whole class. M. Broussais informs us that the causes, the symptoms, and the changes observed in the bodies of those who die of plague, show that the digestive canal is the seat of *the inflammation which constitutes the disease*. If petechiæ, carbuncles, and inflammations improperly called buboes, appear, these symptoms are only according to him, as in typhus, the effects of the sympathetic irritation of the skin and cellular membrane, of which irritation the heat of the climate favours the development.

(Expos. de la Doctrine de M. Broussais dans le Journal Complément. du Dictionnaire, tom. ii. p. 148, 149, et seq.) According to this view, the eruption hitherto deemed characteristic of plague is a mere contingency, and the inflammation of the digestive canal is exalted from an occasional occurrence into the constituent of the disease. It has apparently escaped the writer's observation that the eruption which he attributes to the influence of heat has accompanied the disease in every climate in which it has manifested itself,—in our own in winter, for example, (Sydenhami Opera, p. 108. *De Foe*, History of the Plague, p. 266); and that the affection of the intestines is indicated only in a small proportion of cases, either by symptoms during life, or by the pathological condition of parts after death. The analogy between the petechiæ, which only occasionally appear in typhus, and the characteristic eruption of plague, is too remote to identify these diseases, though we would willingly admit that they are in some degree related, as all febrile disorders are to each other. Professor J. P. Frank places plague in the same genus with continued nervous fever, which is, he says, a fever occasioned by causes acting especially on the nervous system, and which escape the observation of the senses; and this fever, he informs us, may be complicated with gastric and other inflammations, (*J. P. Frank*, De Curandis Hominum Morbis, Epitome, t. i. p. 30, et seq.); an opinion in which we fully concur with him; though we do not agree in thinking plague a mere variety of continued nervous fever or typhus, but, on the contrary, we deem it an independent disease which preserves its character in all climates and situations in which it may exist.

The strongest analogy with plague which we have any where found occurs in the following example of disease, induced, as it would appear, by exposure to the effluvia of common putrefying animal matter.

An American merchant-ship was lying at anchor in Whampoa Roads, 16 miles from Canton. One of her crew died of dysentery. He was taken on shore to be buried. No disease of any kind had occurred in the ship from her departure from America till her arrival in the river Tigris. Four men accompanied the corpse, and two of them began to dig a grave. Unfortunately they began in a spot where a human body had been buried about two or three months previously. The instant the spade went through the lid of the coffin, a most dreadful effluvium issued forth, and the two men fell down nearly lifeless. It was with the greatest difficulty their companions could approach near enough to drag them from the spot and fill up the place with earth. The two men then recovered a little, and with assistance reached the boat and returned on board. On the succeeding morning, they presented the following symptoms: very acute headach, with a sense of giddiness and dimness of sight, (which had existed more or less from the moment of opening the grave;) eyes of a peculiar muddy appearance; oppression about the præcordia; dull heavy pain in the regions of the heart and liver, with slight palpitation at times, and fluttering pulse; sense of extreme debility, with occasional convulsive or spasmodic twitchings of the muscles of the lower extremities; nausea; slight diarrhœa; rigors, succeeded by flushings of the face, neck, breast, and upper extremities; tongue white and much loaded; pulse from 110 to 120, weak and irregular; urine scanty and high-coloured, and skin sometimes dry, sometimes covered with a clammy sweat. On the fourth day from the commencement of the attack, numerous petechiæ appeared over the breast and arms, and in one of the patients a large bubo formed in the right groin, and another in the axilla of the same side, which speedily ran to suppuration. To one, the disease proved fatal on the evening of the fourth day; to the other, on the morning of the fifth.

On examination after death, in both cases the vessels of the brain were found loaded, and an effusion of lymph existed between the tunica arachnoidea and pia mater; there was an unusual quantity of fluid in the ventricles, and upwards of three ounces of dark-coloured liquid at the base of the brain. The optic nerve of the right side, in one of the patients, was surrounded, where it emerges from the thalamus, by a portion of gelatinous matter, and appeared thickened and discoloured; and the surface of the brain was very vascular. The heart in both cases was much enlarged, and distended with blood. In one case, five ounces of a dark-coloured fluid flowed from the pericardium when slit open, and the vessels on its internal surface were gorged with blood, and this was indeed the case throughout the whole portal circle. The stomach, near its pyloric orifice, was thickly beset, in one case, with small purple-coloured spots. The intestines in several places assumed a brownish appearance, as likewise the omentum. There were numerous petechiæ on the surfaces of both bodies. In one of the cases, the medulla spinalis, in the dorsal region, to the extent of three or four inches, was of a light brown colour; and in the other case it exhibited evident marks of congestion throughout. Most of the inguinal and axillary glands were enlarged and hardened, and several of them, when cut into, contained a light straw-coloured matter. No other morbid alteration of structure existed.

One of the two men not immediately engaged in digging the grave was attacked on the eighth day from his being on shore. The symptoms resembled those in the preceding cases. For three days previously to the avowed attack of illness, there had been pain and enlargement of one of the inguinal glands, which, at the period he was visited, had acquired the size of a hen's egg; and early in the disease the breast and arms were covered with petechiæ. By active treatment this person recovered, as likewise did the fourth man, who had slight indisposition of no decided character. (Medico-Chirurgical Review, N. S. vol. ii. p. 202, et seq.)

Systematic writers have generally been more struck with the analogy between plague and eruptive diseases, than with its relation to typhus or any form of idiopathic fever, and hence it is universally found in nosologies placed among the exanthemata. But this analogy is not so complete as to cause it to be ranked among diseases which attack persons but once in the course of their lives. Popular opinion in the Levant,

where plague may be considered almost endemic, imposes this limitation on the disease, — an error not destitute of advantage, as it prevents the sick from being deprived of the requisite attendance; and the kind of confidence it is calculated to inspire is to a certain extent justifiable, as second attacks are unquestionably rare. Dr. Russell informs us, for instance, that he met with only twenty-eight examples of well-ascertained re-infection in four thousand four hundred pestilential cases. This accurate observer cautions us, however, against regarding this as the precise proportion in which second attacks occur, there having been no plague at Aleppo for eighteen years previous to the appearance of the epidemic he describes; and he found great difficulty in obtaining accurate information, after so long a lapse of time, as to the sickness of his patients, or their exemption from disease, during the former visitation; and the number stated must be understood to comprise the double attacks which took place from 1760 to 1762 only.

This opinion of the liability of sufferers from plague to second attacks, is not universal among writers on the subject. The Chevalier Butel, for instance, is of opinion, from personal observation, that an attack of plague in Egypt furnishes complete exemption from all future accidents of the same nature, though, with some inconsistency, he subsequently quotes the case of an English physician, (perhaps he alludes to Dr. Whyte,) who died of the natural disease six months after an attack he had inflicted upon himself by inoculation. (Journal Universel, Jan. 1826.)

Authors on plague, however, who at all revert to this question, are almost unanimous in regarding second attacks as, at least, occasional, if not frequent occurrences. Diemerbroeck mentions several, and, among others, that of a Chevalier Schabhals, a bold and rash man, who was attacked with the prevailing disease, indicated by violent fever, a bubo in the groin, and three carbuncles, from which he had the good fortune to recover. He consequently became so presumptuous as to neglect all precaution, and was again attacked, five weeks after his complete convalescence, with the malady, of which he died before the sixth day. (De Peste, lib. iv. hist. 37. 45.) There is reason to think that some writers have exaggerated the proportion of second attacks from not having duly discriminated such attacks from relapses; thus it has been urged in evidence of the frequency of second invasions, that *convalescents* employed as nurses about the sick, both at Marseilles and with the French army in Egypt, were frequently attacked and perished; but a sufficient number have been noticed by judicious observers to warrant our concluding that plague does not impart that kind of security from second invasions which is afforded by small-pox and certain other exanthemata.

Diagnosis. — Difficulty will never be experienced in discriminating a well-marked example of plague from any other disease, provided the practitioner have an opportunity of observing it throughout its course: for the buboes, carbuncles, and other external affections attending it, constitute, with the intense fever, a group of phenomena which belongs only to this malady. But, on the first appearance of an epidemic, a difficulty, arising from various circumstances, has not unfrequently been experienced in pronouncing on the character of the disease. In the first place it often happens that the early cases belong to the intense type, in which death occurs before the characteristic eruption has time to display itself; and, again, even in cases which ultimately assume the normal form of the disease, a certain period elapses before buboes, carbuncles, or other external marks appear. The symptoms on which—the eruption excepted—most reliance is placed for discriminating plague, are the peculiar inflamed appearance of the eyes, which was previously mentioned, swelling of the tongue, difficulty of articulation, and tottering gait. Of these phenomena, the Chevalier Butel declares that the two first are never absent in any case of plague; but it seems more than questionable whether they belong so exclusively to this disease, that we could pronounce from them alone on the nature of any case we might witness, especially at the commencement of an epidemic, unless our diagnosis were aided by extrinsic circumstances; such as our being aware of the arrival of persons or goods from infected districts, of the sufferers having had intercourse with such persons, or having been exposed to effluvia from the goods, &c. Should such circumstances be shown to have occurred to the subject of a suddenly fatal disease, it would certainly be advisable to act on the assumption of its being pestilential, and to take the precautions which the safety of the community requires. Prudence would dictate, also, that suspicious cases, which do not terminate so rapidly, should be kept secluded for a period sufficiently long to allow their real character to manifest itself, more especially if the disease occurred in a country or district of which the geographical or commercial relation with territories in which plague was prevailing was such as to render its importation a probable event.

Mortality and Prognosis.—Plague is one of the most fatal diseases which afflict human nature; and the general prognosis in the event of its introduction into any place must be in the highest degree unfavourable, unless the early cases admit of being so totally secluded that any general contamination of the inhabitants may be prevented. Very accurate statistical details, from which we may estimate the amount of ravage it generally commits in proportion to the number affected, or to the population of the place or district in which it prevails, are scarcely to be procured, since plague has not proved in modern times a disease of the more civilized nations of the world; and it is only among a civilized people, and at a very recent period, that any thing like very precise records of the fatality of disease is to be found. But such information as we possess leads to the conclusion that of those attacked with plague, fully fifty per cent. perish. At Marseilles, for example, in 1720 and 1721, it is calculated that of a population of 90,000, 40,000 fell victims to the disease, though more than 10,000 are supposed to have escaped infection, (Traité de la Peste, p. 464;) whilst the following returns from the hospitals, and, as it would seem, from certain corporate bodies, show a rate of mortality higher than this general average:

	Received.	Died.
L'Hôpital de la Charité, from the 3d of October to the end of February.....	1013	585
L'Hôpital de Jeu de Mail, from October to the 3d of July.....	1512	820

Of 100 manufacturing hatters, there died 53; and of 134 house-carpenters, 84. The tailors, who were in number 138, lost 78. Of the shoemakers, who were 200, there died 110; the cobblers were reduced from 400 to 50; and of 500 and odd masons, there perished 350. Of persons in a still lower station of society, such as porters and chairmen, the mortality was very great indeed; scarcely a sixth part remaining at the close of the epidemic. (Relation Historique de la Peste de Marseille, p. 437, 438.)

In the capital of our own country, the ravages of plague have occasionally been very great. Thus, of the last five epidemics, those which prevailed between the close of the sixteenth and the latter part of the seventeenth century, there perished, in that of 1593, between March and December, 11,166; in that of 1603, the mortality amounted, between the same periods, to 29,992; in that of 1625, to 34,754; in that of 1636, commonly called—not from the amount or rapidity of its fatality, but from its having lasted twelve years—"the great plague," 11,000 died between April and December of the first year; and in that of 1665 the mortality, for the same period, amounted to 69,602.* But the estimates transmitted to us furnish neither the proportion of deaths to the number treated, nor to the amount of population amid which plague prevailed; for it was so customary for individuals to fly from London on its first appearance, that population returns, however accurate, fail to supply the requisite information on the second point. Defoe (but we do not regard him as very precise authority) estimates at two-thirds, the proportion of the population of London which fled in 1665. Thus much seems certain, that these returns record a difference in the amount of mortality in the same place but in different epidemics, which no supposable variation, either in the amount of stationary population, in the number of fugitives, or in both conjointly, can possibly explain.

It thus appears that we are deficient in statistical details whence to draw a general prognosis, and that, even if we possessed them of the utmost accuracy, (epidemic visitations of the disease varying so much in intensity even in the same district,) they would not furnish secure grounds for estimating the probable danger to a population from an attack of plague. Observers, however, are almost unanimous in marking in every epidemic three periods at which the fatality, and consequently our predictions, must vary. At the beginning of a pestilence, the disease, though less diffused than it subsequently becomes, appears in its most fatal form; during the increase and height of an epidemic, though many more persons are attacked, the comparative mortality is diminished; and during its decline there is a decrease at once in the numbers attacked and the proportion of deaths. A curious anomaly is, however, pointed out by Dr. Russell, in the last-mentioned law of the disease, namely, that persons in constant communication with the sick, who have resisted infection in the most contagious stages of the pestilence, are sometimes attacked in its decline. (On the Plague at Aleppo, p. 262.)

The circumstances which, independently of the period of an epidemic, should influence our prognosis, must be found in the age and general constitution of patients and the symptoms of the disease. On the former head it is important to remark that young, robust, and vigorous adults are more prone to plague, and are more frequently its victims when attacked, than feeble and valetudinary males, and women and children. (Histoire Médicale de l'Armée d'Egypte, p. 78. Jackson on the Plague of Morocco.) Women often appear to owe their recovery to the supervention of menstruation; but it may be questioned whether this occurrence is not rather an indication of returning health than the cause of it. Of the different forms of the disease which we have endeavoured to describe, that in which the febrile commotion is slight, the system appearing to be overwhelming from the commencement, and not possessing sufficient vigour to throw out the eruption, is the most hopeless; whilst in the mildest degree of the disease, indicated only by the existence of bubo, a favourable result may be always calculated on, unless some gross error of regimen be committed to aggravate a slight into a serious disorder. In an affection of an intermediate degree of intensity, the result can rarely be predicted in an early stage. When there is an amelioration of symptoms with subsidence of delirium on the fifth day, we shall generally find a critical and favourable termination on the seventh; and it is commonly remarked that the fact of the patient's surviving till the eighth furnishes grounds for a favourable prognosis. Intense fever with unabating delirium, attended by the three forms of eruption, —buboes, carbuncles, and petechiæ,—indicates a very dangerous disease, from which recoveries are rare, death frequently occurring from the third to the fifth day. Inferences as to the result may be sometimes drawn from individual symptoms. A copious eruption of buboes is not deemed unfavourable; but buboes and carbuncles conjointly in great numbers betoken a dangerous disease, and one which the constitution frequently proves unable to contend with; and the prognosis is still more unfavourable if petechiæ are superadded. A firm and resisting bubo is a good omen, even though it should have a carbuncle in the centre; whilst one of a soft and yielding consistence is thought to be less favourable. Hiccough, convulsions, cardialgia, diarrhœa, and colliquative sweats, are grounds for an unfavourable augury.

Causes.—So much were early observers of this disease impressed with the evidence of its infectious nature, that in the writings of many of them, the words plague and contagion are used synonymously;† and from this kind of metonymy con-

* Graunt's Natural and Political Observations, &c. London, 2d edit. 1662. A Collection of very valuable and scarce Pieces relating to the Plague, p. 81, London, 1721. London's Deliverance predicted by John Gadsbury, London, 1665. Russell on the Plague, p. 274, 275.

† —— patet et pestem esse omnium morborum qui contagione serpunt, etiam ad distans, contagiosissimam, unde à nostris contagionis solo nomine subauditur *Guill. Beaumontensis*, de Peste, lib. i. 1629.

siderable confusion pervades the works of certain able authors, and among others those of Dr. Read. But how conclusive soever this evidence may be to the majority, there have existed persons, both in ancient and modern times, disposed to deny its validity; and on this account we think it advisable not to confine ourselves to the bare assertion of the fact that plague possesses a contagious property, but to adduce examples of it which may prove of sufficient force to convince those who might be influenced by the doctrines of certain very well-intentioned but dangerous speculators.

We have already quoted the opinion of M. Foderé, that plague may be generated by the abundant endemial causes existing in Egypt, which this writer in common with many others regards as the father-land of the disease. Having had no opportunity from observation of verifying or refuting this opinion, we shall leave it a matter undecided, whether all the visitations of plague arise from a permanent stock of human contagion, occasionally receiving increments from the subjects of the disease, when the atmospheric influence is favourable to its diffusion, and occasionally lurking in fomites to burst forth at a suitable season; or, whether the malady is engendered from time to time by the endemial causes we have mentioned, and there is consequently a reproduction of the contagious principle in Egypt. But though disposed to leave this question undecided in the case of Egypt or other eastern realms in which plague seems to be naturalized, we must express an opinion that its appearance in Western Europe has been owing to imported contagion—an opinion which is supported by a host of the greatest authorities that are to be found on this or any other question of pathology. Sydenham, though by no means inclined to exaggerate in any case the influence of contagion, and considering the co-operation of a peculiar atmospheric disposition or constitution essential to the diffusion of plague, yet thinks this pestilential constitution inadequate to its production without importation by fomites or the arrival of a diseased person from an infected district.* To the authority of Sydenham might be added that of Mead and others of the greatest reputation in medicine; but in a question of this nature we prefer to the weight of great names, facts illustrative of its importation, and of its possessing contagious qualities not exceeded by those of any disease whatsoever, and sufficient to account for its diffusion through countries not guarded against it by rigorous quarantine.

The proofs we shall adduce of contagion will be derived principally from the history of the plague at Marseilles in 1720, this being one of the most accurately reported of European epidemics. Its importation into the city appears to have taken place by means of a vessel commanded by Captain Chataud, which left Seyde with a rich cargo on board on the 31st of January, her bill of health being clean, by which is meant that both the place and the ship were free from the disease at the time of sailing; but it was afterwards learnt that it existed avowedly in the town a few days after. The vessel then touched at Tripoli, which is near Seyde, and had constant communication with it, in order to undergo some repairs. Here additional goods were taken on board, and some Turks embarked to be conveyed to Cyprus. One of these Turks fell sick and died in a few days. Two sailors who touched the dead body sickened and died after a short illness, and in a few days after other two persons, one of whom was the surgeon of the vessel, took the disease and likewise died. The captain, becoming alarmed, secluded himself from his crew, and three more men falling sick, and there being now no surgeon on board, the vessel was put into Leghorn. The disease of the three men last attacked was fatal at Leghorn, and Captain Chataud received from the medical men of the place a certificate that they died of pestilential fever. The ship reached her ultimate destination, Marseilles, on the 25th of May, and was put under quarantine of merchandise for forty days. On the 27th another of the crew died. At this time three other vessels from the same suspected places arrived, those of Captains Aillaud and Fouque, and the barque of a second Captain Aillaud. On the 12th of June the vessel of a Captain Gabriel likewise reached Marseilles from the same ports. These ships had all foul bills of health, declaring that at the time of their departure there was a suspicion of plague. The goods of all these vessels, as well as those from Captain Chataud's ship, were landed in the infirmaries for purification.

The disease and mortality continued on board of the first vessel. On the 12th of June the individual placed on board as a guard during the quarantine died, and on the 23d a cabin-boy sickened, and at the same time two porters employed in the purification of the goods, and subsequently a third similarly occupied with those of Captain Aillaud. The disease in all these persons was the same, and all died in two or three days. On the 5th of July two porters, shut up with the merchandise of Captain Chataud, were attacked, and had buboes in the axillæ; and some days after the priest who administered the sacrament to these men died. The passengers from all these vessels, even those from Captain Chataud's ship, were admitted into the town on the 14th of June with their baggage and private merchandise, after their persons and goods had undergone *fumigation*.†

The first case in the town occurred on the 20th of June, and on the 28th of the same month a tailor was attacked and perished, with his whole

La peste, uno dei piu terribili mali che possano affligere il genere umano, benche non sia propriamente lo stesso che il contagio, pure suole avere fra noi il nome di contagio perche toccare i corpi, o l'aria degli appestati; o le merci, o robe, loro, se ne infettano i sani, con piu forza e strage che non accade in altri morbi, epidemici et attacaticci—il perche contagio suo l'anche appellarsi la peste. *Muratori*.della Peste, edit. 4. 1743.

* Interea aëris dispositionem quantumvis λοιμώδη pesti suscitandæ per se imparem esse vehementer suspicor; quin pestilentiæ morbum alicubi semper superstitem aut per fomitem, aut per pestiferi alicujus appulsum, e locis infectis in alios deferri; ibidemque, non nisi accedente simul idoneâ aëris diathesi popularem fieri.—*Sydenhami Opera*, sect. ii. cap. ii.

† The expression in the original is "parfums." The nature of these perfumes is not mentioned, but the author of the Relation Historique censures the quarantine department for their excessive confidence in them, and the neglect of ventilation. (Relation Historique de la Peste de Marseille, p. 35.)

family, after a few days' illness. On the 1st of July a woman named Ligazière, living at the foot of the Rue de l'Escale, was attacked with the disease, and had a carbuncle on her nose; and immediately after, a woman named Tanouse, in the neighbourhood, took the disease, and had buboes, and from her the whole street appeared to have become contaminated, the contagion invading first the houses adjoining that of Tanouse. (Relation Historique de la Peste de Marseille, p. 26—38.)

It was from this street (Rue de l'Escale) that the disease was introduced into the Hotel Dieu, through which its progress is one of the strongest evidences of contagion that is to be found any where recorded. This hospital was closed against pestilential cases and all that had communication with them, it being intended to reserve it for the patients who occupied it at the time of the breaking out of the disease, those who might be attacked with other disorders besides plague, and between three and four hundred children (enfans trouvés) who were its permanent inmates. A woman, who had escaped from the street we have mentioned, applied for admission, and either the characteristic marks of plague not having appeared, or having escaped the observation of the examiners, she was supposed to labour under ordinary fever, and was received into the house. She was conveyed by two girls into the women's apartment, and the principal nurse changed her linen. On the following day the two girls sickened, and died after an illness of six or eight hours; on the day after this, the nurse became ill and died almost as suddenly. From these four patients the disease spread rapidly through the house, and *all its inmates*, directors, confessors, physicians, surgeons, apothecaries, and all the other officers, servants, and nurses *perished*, excepting thirty of the children, who were the sole survivors from a number of persons amounting to between five and six hundred. (Relation Historique, p. 94, 95.)

The effect of seclusion was exemplified in the case of the convents of nuns, all of which cut off communication with the town, and remained exempt from the disease throughout the whole of the pestilence. The Poor-House (La Charité) adopted the same precaution, and enjoyed the same exemption till the end of September. It was then converted into a pest-hospital, its original inmates being removed with the exception of a few who were retained as nurses; of these almost all perished. (*Deidier*, Traité de la Peste, p. 353.) The exemption imparted to religious communities by seclusion was strikingly contrasted with the ravages of the disease amid the orders of ecclesiastics who were employed in offices about the sick. Of the order of capuchins, who furnished a great number of confessors to the town and hospitals, forty-three perished, out of the whole body of fifty-five. (Relation Historique, p. 177.)

The contagious nature of plague is strongly exemplified, in the early stage of epidemics, by the gradual manner of its diffusion, the paucity of the attacks at the commencement, and their slowly increasing in frequency, till, foci of contagion being multiplied, vast numbers are invaded at the height of the disease. The rarity of the early invasions at Marseilles, and the havoc it ultimately committed, have been described. A similar mode of progression is observable in all epidemics of plague. In that of London of 1603, the number of deaths were progressively as follows: in March 11, April 26, May 83, June 362, and July 2999; in that of 1625, in March 23, April 85, May 224, June 954, July 5887; in that of 1636, April 37, May 162, June 440, July 456, August 1239, September 3856; in that of 1665, April 2, May 43, June 1060, July 5667.

We need not, as it appears to us, enlarge further on the evidence of contagion in plague, enough having, we trust, been adduced to convince the most sceptical. It appears transmissible from individual to individual in all the ascertained modes in which diseases are thus communicated; by contact, inoculation (from the matter of buboes), through the atmosphere, and by fomites. Observers have endeavoured to illustrate certain obscure points in these different modes of transmission. Thus, with regard to the matter of buboes or of sinuous ulcers consequent on them, it has been conjectured that its contagious property ceases before the healing of the sore; but no precise conclusion having been attained regarding the period when this cessation takes place, Dr. Russell advises that all pestilential ulcers should be held infectious till after the expiration of two months from the first attack, and the patient secluded accordingly. The contagious distance from the person of the patient has been matter of discussion, some persons imagining that a degree of proximity almost equivalent to contact is necessary for the communication of plague; but there is reason to think that this circumscription is much narrower than facts justify us in drawing it; though it is probable that the effluvia when once transmitted into pure air are soon blended with the common mass, and suffer such alteration as renders them innocuous at no great, though not an ascertained, distance from the patient. At what period of the disease the communicable property commences, and how soon after convalescence it ceases, are points which may be considered quite undecided. The most accurate observers are of opinion that consciousness of receiving infection, a feeling occasionally discerned in ordinary contagious fever, does not occur in plague. (*Russell*, p. 302.) When received, it does not hang ambiguously about a person in any case for more than two or three days, but its operation once announced by visible signs of disorder, the progress of the disease is rapid, there being a difference in this from the course frequently observed in typhus, in which the effect of contagion on the system is frequently manifested by slight indisposition, sometimes lasting for weeks, previously to the complete formation of the disease. (See Contagion.)

It would be desirable to ascertain the duration of the latent period of pestilential contagion from its reference to the safety of intercourse between infected and healthy districts; but the information to be obtained on this important question is of a very unsatisfactory nature. Only at the beginning of a pestilence, when foci of contagion are rare, can any attempt be made to illustrate it, and hence the data are too scanty to furnish a conclusion which can be implicitly relied on. Dr. Russell has known the disease sometimes manifest itself a

few hours, and in some cases two or three days after intercourse, and is disposed to consider that infection rarely remains latent beyond ten days; but he acknowledges that wider experience is required to determine positively the latter point. The period during which contagion may adhere to unventilated goods appears as unascertained as the latent period in the case of persons; but many circumstances lead to the belief that it is of considerable length.

The question has been raised whether dead bodies have an infecting power, and M. Desgenettes answers it positively in the negative; but there is much reason to think that this decision is too general, however warranted by the experience of its author. During the pestilence at Marseilles, burying the dead was found so dangerous an operation, that free persons could not be procured to perform it, even for an enormous recompense, and consequently the galley-slaves were employed, on a promise of liberty when the duty should be completed. They were sent out in detachments. The first, consisting of twenty-six, were all attacked with the disease in two days, and successive numbers were sent on the duty, till, from the 20th to the 28th of August, one hundred and thirty-three had been employed, when the officers of the galleys refused to send any more, almost the entire number furnished being either sick or dead. It was likewise observed in the plague of London of 1665, that officiating at funerals was an office fraught with extreme peril.

Certain conditions of the atmosphere influence the diffusion of the contagion of plague, or the susceptibility of bodies to be affected by it. Of these, the most manifest is temperature, extremes in this respect checking, and warmth within a certain degree appearing to favour, the propagation of the disease. It hence occurs that the abatement of pestilence in the east takes place during the heats of summer, and in Europe in winter. Popular superstition among the Christians resident in Europe, fixes on St. John's day as the exact period of the cessation of pestilence: we scarcely need remark that this opinion is much more precise than is justified by facts. The following, according to the most accurate observers, is the ordinary course of the diminution and ultimate disappearance of plague in the Levant. There is a manifest abatement of the disease at the commencement of the summer heats, and in proportion as these continue and increase, cases become more and more rare, and finally cease; while contaminated goods lose at the same time, as we are informed, their infecting property. The uniformity in this course is so great that Christians who shut themselves up during pestilence, almost always come abroad in June, the instances being very rare in which they remain confined to July. Epidemics in Europe have generally commenced in spring, or in the beginning of summer. Autumn has frequently been the period of their greatest prevalence and fatality, and they have either been totally extinguished in winter, or have then received a very considerable check, and have finally ceased in the early part of the ensuing spring. The great plague which prevailed in London from 1636 to 1648, presents an exception to this rule; but during this extensive period there was invariably a diminution of cases in winter, though at no time a cessation of the disease.

Independently of manifest atmospheric conditions, that inscrutable state of the air to which the term epidemic constitution has been applied, so much influences the propagation of plague, that certain very experienced writers have denied its possessing a communicable property, unaided by this atmospheric peculiarity. In illustration of this view, Dr. Russell informs us that experience in Turkey, where generally no precautions are taken in times of pestilence, clearly evinces that in a certain state of the air a communication with infected places may subsist without any material consequences. The return of plague at Aleppo happens at irregular periods; the intervals are of considerable but unequal length; and in these, the commerce with Egypt, Constantinople, and Smyrna, remains uninterrupted. In the intervals between 1744 and 1760, and from 1762 to 1780, the plague raged several times in the places now mentioned, without affecting Aleppo; and even in two or three years subsequent to 1762, though it was at Marash, as well as other places not far distant, with which Aleppo has continual intercourse, no instances were discovered of communicated infection, and this exemption continued, notwithstanding that infected families from some of these places took refuge in the town. It would appear, moreover, that this constitution, favourable to the progress of plague, varies considerably in degree. Thus we learn from the able author last quoted, that the progress of plague at Aleppo was exceedingly restrained in 1760; it was much more vigorous in 1761; it raged with great fatality in 1762, and in this year was finally extinguished, though there was no appreciable difference in the state of the seasons in the respective years to explain the varying diffusion of the disease, or its ultimate extinction. To the cessation of this atmospheric condition, which is known only by its influence on the propagation of disease,* is to be ascribed the occasionally sudden and otherwise inexplicable disappearance of plague in oriental countries, where no disinfecting process is employed. Much, too, that ought rather to be attributed to a change in this latent state of the atmosphere, is frequently ascribed in other countries to disinfecting processes, which are in truth rarely so general or efficient as to account for the cessation of pestilence.

[So many contradictory statements of "facts" have been brought forward, that it is difficult to form any exact opinion either as to the origin or the extension of plague. It is certainly an endemico-epidemic, and this inference is confirmed by the influence of season, which, in plague countries, is a common topic of observation. We have said, that the decrease of plague in the East towards the middle of June is so remarkable, that at Cairo, St. John's Day, which is the 24th of June, is ever understood amongst the superstitious inhabitants to put a period to the disease. The uniformity of its decrease as the summer advances is so

* At vero quæ qualisque sit illa aëris dispositio, a quâ morbificus hic apparatus promanat, nos pariter ac complura alia, circa quæ vecors ac arrogans philosophantium tubra nugatur, planè ignoramus.—*Sydenhami Oper.* sect. ii. cap. ii. p. 107.

marked, that persons, who have previously confined themselves, come forth invariably on that day, mix with other people, transact their ordinary affairs, and restrain themselves, in no respect, from any apprehension that they may take the disease. But although plague is evidently dependent upon locality and season, it has been supposed that a principle may be given off from a plague patient, which, if concentrated, — as in very malignant forms of the disease, and in pent-up situations, where proper ventilation is impracticable,—might cause it in a healthy individual. Such—as the writer has said elsewhere, (*Practice of Medicine*, 2d edit. ii. 509,)—*may* be the case; but by many, who have had ample opportunities for observing the plague, it has been denied,—and the negative view is strengthened by facts communicated to the English Admiralty by Sir William Burnett.

In a recent work, Dr. John Davy, (*Notes and Observations on the Ionian Islands, &c.*, London, 1842,) gives many examples to show that, taking it for granted that the disease is contagious, it is but very slightly so; and hence there is a necessity for a revision of the quarantine laws, "with a fair prospect" — to use his own words — "of their being greatly mitigated, and at the same time rendered efficient, to the great comfort of the traveller, the incalculable advantage of commerce, and the universal benefit of mankind."]

Treatment.—There are few points in medicine on which greater discrepancy of opinion prevails than the mode of treatment to be adopted for conducting patients safely through this dangerous disease. Remedies which are the favourites of one class of observers, in the hands of others prove to be fraught with danger. Bloodletting, emetics, and other heroic measures, are alternately lauded as cures and censured as poisons. We believe that had any of the remedies, the reputation of which has been so fluctuating, been announced as cures for any of our ordinary epidemics, such as small-pox, scarlatina, or continued fever, without reference to the period or type of the disease in which they were to be employed, the testimony for and against them would have proved equally conflicting. The general treatment of any epidemic, independent of that required to combat local lesions, may be comprised, if we mistake not, in few words:—We must deplete the excited, and stimulate and support the sunken and collapsed; and in an immense majority of instances, the condition requiring the former means, if it exist at all, will be found in an early stage of the disease; that demanding the latter, will occur in an advanced period.

The best authorities inform us that bloodletting is to be employed at the very commencement of the disease, if the pulse possess sufficient force to render such a proceeding prudent; and some are of opinion that a second bleeding may be occasionally admissible; but that very judicious observer, Dr. P. Russell, cautions us against performing any bleeding after the third day. He mentions, however, one case (On the Plague at Aleppo, case ciii.) in which bleeding was successfully performed on the third day from both arms at once, though the patient, a female, had been bled the preceding day. The presence of buboes, which Sydenham and others have regarded as a valid objection to bloodletting, from a dread that the operation might occasion their recession, ought not, we are assured by more recent authorities, to prevent its employment, as neither the eruption nor progress of these tumours is injuriously influenced by it. Dr. P. Russell, indeed, remarked, that where the pain of buboes was excessive, bleeding was necessary to moderate that and other inflammatory symptoms, for till the fever declined, these tumours never advanced kindly to suppuration.

Many cases, however, occur, in which the collapse of the system is so well marked from the commencement that the employment of bleeding is manifestly inadmissible, and emetics are then thought the most suitable remedies. Should the first emetic dose fail to act, it is advisable to repeat it after the interval of an hour or an hour and a half. Full vomiting, we are assured, especially if bilious matter or worms were discharged, was found so efficacious during the prevalence of plague at the city of Aix in Provence, that almost all from whom such matters were ejected recovered, whilst those on whom the emetic failed to operate perished. (*Sauvages*, Classes Morborum, vol. ii. p. 368.) It is probable that the failure of emetics was not so properly the cause as the token of death, as it indicated an extremely collapsed state of the system, of which the sensibility was almost annulled by the vehemence of the disease.

Purgatives are generally regarded as suspicious remedies, from the tendency to diarrhœa being so general in the disease, and its very fatal effects; and practitioners concur in declaring costiveness to be less prejudicial in plague than other febrile disorders. The irritability of the bowels is so great, and hypercatharsis is consequently so liable to be produced by the more active purgatives, that we are advised to empty the bowels at the commencement of the disease by means of the most lenient of the class, such as cassia pulp, manna, or rhubarb, with cream of tartar. Sir Brooke Faulkner, however, employed calomel and jalap, without intimating that inconvenience resulted from the practice. (Treatise on the Plague, p. 238.)

Among the older physicians, the object of whose practice was to eliminate from the blood the noxious principle on which they conceived the phenomena of the disease depended, the more heating diaphoretics, such as contrayerva and serpentaria, were favourite remedies, whilst their operation was aided by excluding the air, heating the apartment, and heaping the patient with bedclothes. This method of treatment, so injudicious in any febrile disorder, is now universally abandoned by European practitioners. Some of the more cooling sudorifics, as liquor ammoniæ acetatis, and saline draughts, are customarily given by many physicians, and by some are thought to be beneficial. Dr. P. Russell says that saline draughts given in an effervescing state are much more efficacious in checking the retching which is sometimes a distressing accompaniment of plague than that of ordinary malignant fevers.

It has been stated that diarrhœa is a very common and very dangerous symptom. The judicious observer we have so frequently quoted, Dr. P Russell, informs us that he was at first unwilling

to administer opium for its relief, from an apprehension of aggravating the stupor or comatose disposition; but finding that this effect did not follow its employment, he used it in 1762 much more freely than he had done in former years, and in general remarked that where he succeeded in stopping the looseness early in the disease, the patient became more alert and sensibly better. In the more advanced stage, however, we learn from the same writer, astringents and opiates rarely checked or suppressed the diarrhœa. Inflammation of the intestines being one of the few pathological appearances generally recorded by authors, there can be little doubt that the diarrhœa which accompanies plague indicates some inflammatory affection of the bowels, and that local bleeding, from the integuments of the abdomen or anus, and perhaps subsequent blistering, would be found important auxiliaries in its treatment.

Coma and other affections of the brain it is customary to combat by means of blisters between the shoulders, to the nape of the neck, temples, and occiput. (*Sir B. Faulkner*, loc. cit. p. 241.) It is extremely probable that the dread of drawing blood, which is so general among those who treat this disease, is the reason why local bleeding is not conjoined with the counter-irritants to subdue the cerebral affection. From the symptoms we have detailed of the intellectual disorder in plague, there can be little doubt of its depending upon the same causes as that which accompanies other malignant fevers, and that the same method of treatment would be found applicable to both.

Certain remedies of the general febrile state, besides those already mentioned, have been tried by European practitioners in this disease. Cold affusion is thought by Sir B. Faulkner to present a considerable prospect of benefit if applied at the very commencement: this writer, however, it should be remarked, speaks from a very limited experience of its effects. Several writers speak favourably of mercury; some on merely speculative grounds; others from the analogy, real or presumed, between plague and other disorders in which they have observed that this mineral is useful;—Mr. Stafford from considerable experience. This gentleman declares that, when his regiment was infected, thirty or forty cases of axillary tumour recovered under its use, and he relates at length five severe cases of plague, of which three recovered under mercurial treatment. The mode of administering it was internally, in the form of calomel, and by inunction. The statements of this writer seem to show that the mineral may be serviceable in the treatment of the disease. (Cases by Mr. Stafford, quoted by Sir B. Faulkner, p. 245–253.)

Should the vital powers appear to be failing at any period of the disease, wine and cordials are administered, and many writers advise that they should be accompanied by tonic medicines, of which calumba, bark, and serpentaria are those most usually resorted to.

Friction with oil has been praised as a means of curing the disease, by inducing diaphoresis, and likewise as a preservative from infection. The property of inducing diaphoresis it certainly possesses; but its power of curing the disease is questioned by numerous authorities. A writer whom we have often quoted,—Sir B. Faulkner,—is equally sceptical as to its prophylactic powers. On this point he remarks: "There are so many instances of persons living in the closest intercourse with the infected who escaped without the use of oil, and so few well-attested cases of persons having come into actual contact with pestiferous matter who were protected by oil alone, that I cannot hesitate to conclude that the opinion of its possessing any independent or certain prophylactic efficacy is destitute of foundation." (Op. cit. p. 232.) Vaccination has been recommended as a means of prophylaxis. The last-quoted writer furnishes us with the following forcible argument against its claim to such a property. "I took pains," says he, "to ascertain whether those who had recently been vaccinated were rendered less susceptible; and I found that the instances of its inefficacy were every where numerous, of which I may mention rather a striking one, which was communicated to me by a Maltese surgeon, who was much employed in the plague, namely, that of a numerous family who had been recently vaccinated, the whole fell sacrifices to the prevailing contagion, with the exception of the parents, who had never undergone the operation." (Op. cit. p. 233.) For the prophylactic means to be adopted, we beg to refer to the articles Contagion and Disinfection.

The general plan of diet is the same as in other febrile disorders. Of preparations of animal food nothing stronger than chicken broth should be allowed; the rest ought to consist of preparations of farinaceous or leguminous vegetables, ripe fruits, and simple diluents, such as lemonade, toast-water, or tea.

[It is to be deplored, that all remedial agencies are too often ineffectual, owing to the malignity of the disease; and, accordingly, we are not so much surprised at the information given by Dr. Shapter, (Tweedie's *Library of Medicine*, 2d Amer. edit., i. 230, Philad. 1842,) that a recent observer, after five months' experimenting with all kinds of treatment, and all modifications of the disease, in about 1000 cases, arrived at the melancholy conclusion, that, although the medicines produced their wonted effects upon the organism, the malady neither ceased nor changed.]

The local treatment of buboes should be limited to the application of warm emollient poultices. By the older writers, who erroneously conceived that the suppuration of buboes was the cause, rather than the effect, of the abatement of the fever, various irritating measures were resorted to for accelerating the process, but sounder pathological views have occasioned them to be abandoned. When suppuration has taken place, the matter may be left to discharge itself spontaneously, or the lancet may be employed to give exit to it. Should the original aperture be too small, it should be dilated, as its narrowness is apt to give rise to sinuses. If the carbuncles require topical treatment at all, it should be of the same simple nature as that of the buboes. Prior to the forming of the eschar, a mild poultice only is required: subsequently a slightly stimulating dressing, such as unguentum resinæ, or the same with oleum terebinthinæ, may be interposed between the tumour and the poultice.

Joseph Brown.

PLETHORA, πληθώρα, *fulness*; [*Polyæmia* of Andral.]—Before entering on the discussion to which this article is appropriated, the writer wishes to guard himself against a misconception that has at times been inconsiderately formed respecting the doctrines maintained in it. Though connected with the foundations of all pathology, they are by no means intended to represent the whole of it. Pathology regards living actions, which depend on organized structure, and this both derives its nutrient elements from the blood, and returns to it the effete matter which the nutrient deposits displace. This connection—subsisting without intermission so long as life endures—is so intimate, that whatever affects the condition of the blood must immediately concern the well-being of the whole frame; whence every approach to a correct pathology of the circulation must contribute to the establishment of sound principles, and improve medical science. But pathology embraces more than the mere lesions of the blood or of its circulatory apparatus; there is a nervous system as well as a vascular, which cannot be overlooked. We wish it, therefore, to be understood, that in the following doctrines of plethora we have not the slightest intention of establishing an exclusive pathology, or of claiming for the facts and reasonings adduced a higher importance than they intrinsically merit.

The term *plethora* but ill expresses the state of constitution which it is used to designate, yet it would be difficult to substitute one more correct and appropriate. Indeed, no concise term could convey the compound idea which requires to be represented, and which involves the conception not so much of the quantity of the circulating fluid, as of the relative proportions of its constituent parts. The term hyperæmia, as being of similar import, would not be preferable even if it were not otherwise appropriated. It is applied to denote local accumulations of blood arising from congestion or determination, in which the phenomenon results solely from the increased quantity of blood, without reference to its quality, and is consequently expressed with correctness by a term representing such excess.

Plethora, though inducing a morbid condition of the body, has not in general been designated a disease, nor treated of by practical writers, save in connection with some special malady attendant on or derived from it. Linnæus has given it a place in his nosology in the class *Deformes* and order *Decolores*, and thus defines it: "Rubedo corporis a distensis vasis sanguineis, cum dyspnœa." Sagar also admits it in the class *cachexiæ*, and order *Intumescentiæ*, giving not only a definition but a description also: "Intumescentia universalis, proportionata et æquabilis ex abundantia sanguinis." "Amystidis et ventris cultus, pulsus plenus aut suppressus, venarum amplitudo conspicua, æstus et gravitas totius corporis, respirandi difficultas, lassitudo spontanea, stupor artuum, somni turbati, partes epidelio tectæ ruberrimæ, temperamentum sublaxum, sanguineum." The former of these would seem to denote rather special disease of the lungs, and the latter to characterize obesity. Neither is calculated to convey a clear or correct notion of the morbid condition which excess of blood occasions. As this condition is present in many diseases, and actually gives rise to several; and as, even in cases where it does not exist, it is of importance to be assured of the negative, it cannot but be deemed an important part of pathological science to trace the circumstances which generate a state of plethora, and the phenomena which indicate it, so as to be prepared both to recognise it when present, and to apply means suitable and adequate for its correction.

Disease is considered to exist when there is any observable deviation from health in any of the functions or structures of the body. When the whole constitution is disturbed or depraved, without any part being prominently affected, the disease is said to be general or constitutional, and according to its character is called either febrile or cachectic. If any function or organ be particularly disturbed, a name is thence affixed; and if an organ or function suffer without apparent disturbance of the general health, the disease is pronounced local. On such views have classifications of diseases been formed, yet are they wholly wanting in that precision which the productions of a nosological arrangement should indisputably possess.

When morbid symptoms of any kind arise, it is necessary to consider not only the morbid lesions which immediately produce them, but also the deviations from health in which these morbid lesions themselves originate, tracing these back to the point where deviation from health first occurs. By such investigation only can the history of disease be rendered complete, or its true pathology be established.

It is easy to understand why the investigation of disease has for the most part commenced with that period when a nosological malady is considered as formed. Until this period arrives medical aid is rarely sought for, the patient's consciousness of indisposition being aroused only when the functions of health become so impeded as to fail sensibly in their accustomed exercise. The accession is then referred in general to some exciting cause, real or imaginary, and is considered as having commenced at the time when the imputed cause was supposed to operate, a state of previous good health being assumed. Thus suddenness of accession has been regarded as a character of most acute diseases, and the period when the accession has been first observed has been regarded as identical with the commencement of disease. Yet it may be doubted whether any disease, excepting such as results from a morbific poison, ever takes place suddenly or without previous derangement of general health, cognizable by its appropriate manifestations, and capable of being corrected so as to obviate the morbid accession to which it leads. If this can be demonstrated, it is clear that this introductory stage of disease is of the highest importance, as being that to which prophylactic treatment can be most beneficially directed, and also as forming a part of the ensuing disease essential to its complete history, and without a knowledge of which its intimate nature or the series of morbid changes never can be thoroughly understood.

In tracing the progress of plethora, and the derangements of function which it occasions, it is necessary to commence at that point where the

equable and temperate exercise of all the functions of life constitutes the state which we denominate health. By this means physiology becomes connected with pathology; the actual transition of health into disease is elucidated; and a light is thus shed on morbid processes which no other source of investigation can supply. When disease has made a certain advance, and continued a certain time, so complex are the derangements resulting, that without some clue for unravelling their intricacies, an exposition of them is in vain attempted, and, as the history of physic abundantly shows, conclusions the most opposite may be arrived at in inquiries directed to the same end. This could not be the case if the several morbid changes, as occurring in the respective functions, were marked in their regular progression, so as to determine, when any one presented, what were its antecedents, what would be its consequents. Were this knowledge clearly possessed, each symptom of disease would be discriminated as belonging to a determinate train of morbid actions; and however obscured it might be by contingent or derivative disturbances, it would point out unequivocally the appropriate means of its own correction. With such accurate knowledge we should not see such ambiguity prevailing as that in certain maladies some practitioners enjoin bloodletting where others give opium and ammonia.

Almost all systematic and theoretical writers have left their inquiries incomplete; with each an important stage of the disease of which they respectively treat remains unexplained. This stage embraces the interval between the first deviation from a state of health, and the occurrence of the special lesion of which each has taken cognizance; and it is chiefly to this stage that we propose to direct attention in the following pages.

The constant unremitting exercise of the functions, the aggregate of which constitutes all that we know or can conceive of life, is attended with a physical expenditure which daily nutrition replaces. The nutritive matter taken into the stomach, and which forms the chief support of animal life, undergoes several successive changes in its passage through the body; it is digested, assimilated to the animal juices, deposited in the several structures for their appropriate nutrition, and finally, when no longer fit for supporting their healthy actions, is taken up by the absorbents and carried out of the system by appropriate excretories. It is obvious that there is a natural proportion between the ordinary waste of the body and the supply of fresh nutritive matter, and that if the latter be either too sparing or excessive, the functions of life must undergo some deviation from their healthy exercise.

Considerable variations are liable to occur in the quantity and quality of food which any individual consumes, in the assimilating processes by which what is taken into the stomach is animalized and fitted for repairing the waste of the system, and in the several secretions in which the blood is expended. If more food be assimilated than the ordinary waste of the body requires, a state of repletion must be the natural and inevitable result. But repletion may also take place under a moderate and even abstemious use of food, when, from sedentary habits, inactive life, or other cause, appropriation of blood by the nutrient and other secretions is languid and inefficient. As repletion, then, may take place under very different circumstances, so is its presence marked by different phenomena. Whenever it arises, one of two consequences is sure to result; either it excites the several functions, if sufficiently healthy and vigorous, to increased actions leading to its speedy appropriation and removal; or, if these be weakly and unable at the moment to institute and support those increased actions by which the redundant matter is to be appropriated and expelled, then, oppressed by a labour to which they are unequal, they manifest a decline of even their ordinary power, and all the outward phenomena of debility are displayed. To discriminate this state from one of real debility arising from exhaustion of animal power, or from defective nutrition, is a matter of practical importance not inferior to any which medical science may be engaged in illustrating.

When redundancy of nutriment takes place in a healthy constitution, its earliest effects manifest what may be termed rather exuberance of health than a state of disease. The several functions of the body are more vigorously performed, the nutrition of its several structures is more abundant, and it acquires increase of bulk, especially if the habits of life are not of an activity capable of increasing excretion to a degree proportionate to the nutriment inordinately supplied. And if the excess be casual or inconsiderable, the self-adjusting powers of the body are amply sufficient to dispose of it so as to prevent the transition of healthy actions into diseased. If from extent or continuance the excess be such as to urge these powers beyond a certain point, then their conservative energies fail and irregular actions of various kinds take place, laying the foundation of a large proportion of the specific diseases to which the human body is liable. The general character of diseases so induced is inflammatory. They are marked by a quickened circulation, increased heat, and a more or less depraved state of the several functions. According to the predisposition of the system, hereditary or acquired, to the accidental weakness of particular parts, or to the casual excitement to which the body may be exposed, is the specific form of the ensuing disease determined. For this diseased condition the means of essential relief are, depletion and abstinence; the one to remove or abate the original cause of distemper,—the other to prevent its recurrence. There can be little doubt that the process of nature here referred to, though generative of what we term disease, is yet intrinsically sanative; its object being to dispose by increased energies of that which the ordinary powers are unable to appropriate and the continuance of which is inconsistent with their healthful exercise.

When repletion occurs in a habit of less natural vigour, the self-adjusting powers are not so successful in effecting early restoration, and inflammatory actions are more tardy in their accession. The interval which precedes the occurrence of morbidly increased actions is one of peculiar interest, because its phenomena are of an equivocal character, resembling in many respects those which belong to a very different state of the sys-

tem, and hence liable to be misunderstood; and more especially because they have hitherto been very imperfectly investigated.

The two kinds of plethora here described may be conveniently distinguished by the terms *absolute* and *relative;* the former implying that the redundancy exceeds what the healthy state of the individual constitution would require or bear; the latter that, without being absolutely excessive, it is relatively so in reference to the deficient powers of the constitution for appropriating or otherwise disposing of it. Absolute plethora would thus correspond with the *plethora ad molem, ad vasa, ad venas* of systematic writers; and relative plethora to the *plethora ad vires.* With respect to the *plethora ad spatium,* or that referred to reduced capacity of vessels, the actual quantity remaining the same,—or the *plethora ad volumen,* arising from increase of bulk without actual increase of quantity, it would serve but little purpose to notice them in a practical treatise; the former being resolvable into relative plethora, and the latter, if it ever take place, being only a transitory effect of a temporarily operating cause, such as increased temperature, by which the volume of the blood was supposed to be expanded. The distension of vessels, however, from which this expansion was inferred, was much more probably occasioned by the excitement of the arterial system caused by the stimulus of heat. It is questionable whether a real plethora ad volumen ever occurs except in the instance of persons ascending great heights, at which the diminished pressure of the atmosphere seems to give rise to some such effect.

The subject of plethora might be comprised under the heads of absolute and relative; but its discussion would not then be complete, for so continually is nutritive plethora combined with another source of vitiation of the blood, that it is impossible to do justice to the one subject without at the same time illustrating the other. This vitiation takes place when under moderate nutrition there is defective excretion; in which state the system is oppressed, not so much by the quantity of nutriment, or the labour of disposing of it, as by the load of excrementitious matter with which the blood is overcharged. The phenomena and treatment of this condition of the body are also of high interest, and deserving attentive and mature consideration; for unless its nature be clearly understood, the treatment must be purely empirical, and its success precarious and incomplete. Each of these morbid conditions will now be considered; and the discussion will, we trust, assist in reconciling some of the apparent anomalies and inconsistencies with which medical practice is so frequently charged.

I. To the first of these conditions, or that of absolute plethora, belong all the cases of pure inflammation which we daily witness. It is usual, when these occur, to refer them almost exclusively to the exciting cause which may have immediately produced them. Yet the fallacy of the conclusion must be obvious when we reflect that, of several individuals exposed to the same exciting cause, scarcely two will be affected alike. From exposure to cold, for instance, one will be attacked with catarrh, another with rheumatism, a third with inflammation of the bowels, a fourth with sore throat; while by far the greater number will escape altogether. Were the exciting cause solely chargeable with these several effects, they would unquestionably be marked with greater uniformity. The truth is, that the exciting cause produces its effect because the body exposed to it is prone to be morbidly affected in consequence of its own previous derangement; and the specific form of the disease is determined, partly by the operation of the exciting cause, but chiefly by the predisposition of the parts affected to undergo those morbid actions to which the general indisposition of the system and their own partial weakness render them liable.

To distinguish by its appropriate phenomena that condition of an apparently healthy body, which subjects it to be affected by slight exciting causes, must be an important part of medical knowledge. This state and these phenomena the writer of this article endeavoured to explain and illustrate at some length several years ago. He then made known the course of inquiry by which he was led to investigate these phenomena, and to trace them backwards to the point where health first passes into disease. His earlier observations were conducted on what occurred in his own person, at a time of life when he was prone to severe attacks of inflammation, and when regard for his safety compelled him to watch vigilantly the premonitory indications so as to anticipate the approach of inflammation, and by timely interference avert its more severe accessions. By close attention he was enabled to detect those indications in certain derangements of functions sufficiently clear and undeniable when noticed, but which might, on superficial examination, be overlooked or regarded as trivial and insignificant. The success of his early endeavours to arrest advancing disease encouraged him to observe still more closely, and detect at still earlier periods, the morbid actions introductory to inflammation; in which way he progressively ascended to the higher links in the chain of causation, availing himself always of the knowledge thus acquired so as to apply means of relief at the earliest period when a necessity could be perceived; and with such effect that he succeeded thoroughly in subduing a liability to inflammation, from which he had suffered repeatedly and severely for several years. Engaged in hospital duties of some extent, he had ample opportunity of making corresponding observations in a tolerably wide field of practice; and the result was a full confirmation of all that the experience of his own case had taught him. From the principles thus deduced, the writer has derived much valuable guidance in the investigation and treatment of disease for more than twenty years; an experience which may be considered as justifying some confidence in now again submitting them to the profession through the medium of a work devoted to practical medicine. To detail here the analytical processes of inquiry from which this experience was derived would extend the present article beyond its allotted limits. Premising, therefore, that it was from research so conducted the following information was obtained, we shall proceed to state synthetically what we believe to be the course of morbid actions con-

sequent to and resulting from redundancy of nutritive matter in the blood, both absolute and relative.

We have stated that absolute plethora is the parent of pure inflammation. If there be no plethora, inflammation will not be excited by slight causes; or if it be aroused through the operation of an exciting cause, it will be mild and easily subdued. The severity of inflammation, too, will, *cæteris paribus*, be proportionate to the degree of plethora pre-existing. Previously to the occurrence of febrile or inflammatory action, there is always a sensible interval of disease marked by evidences of diminished power in the arterial system, the oppressed and irregular actions of which evince its inadequacy to carry on the circulation with its wonted vigour. The pulse, if examined, will be found low, oppressed, irregular; which state passes progressively into one of permanently increased action or fever. Multiplied observations have satisfied us both that the stage of disease here mentioned precedes that of febrile action, and that the morbid actions indicated by the pulse succeed each other in the order here announced; the first being that of feebleness or overloaded power, the second of irregularity, and the third of permanently quickened circulation. It has been already stated how incipient plethora, when the redundancy is no longer disposed of by the healthy action of the several organs of appropriation, and when these can no longer perform steadily the increased labour, gives rise to the state of feebleness now under discussion. To comprehend the nature of these several changes is not difficult, it being readily explicable by reference to well-known laws of vital action.

When redundancy of nutritive matter first occurs, its immediate effect is to promote more vigorous circulation, and to excite to increased actions the several capillaries, especially those engaged in nutrient secretion. The peculiar stimulus of the nutritive matter excites these actions; their end is to dispose of the redundancy by natural appropriation, and the effect on the frame in the first instance is only that of increased volume and exuberant health. But to all vital actions, and the degree to which they can be continuously sustained, there is a limit; and when increased beyond this, they after a time become relaxed, sinking even below the natural standard. By incipient plethora increased actions are excited which at first differ from perfectly healthy actions only in degree. In time, however, and especially if the plethoric state be kept up by excessive nutriment, they become enfeebled and abate; then it is that the pulse, which antecedently was fuller and stronger than natural, first becomes low and oppressed. The disposal of redundancy by increased action of healthful processes proving inadequate, from inability of the vital powers to continue it, other efforts are now needed; and as these, though in their tendency corrective of what is amiss, no longer resemble the healthy actions, they must be considered as morbid; disease being the result of their institution. While we thus regard them, however, we should never lose sight of the corrective tendency which originally belongs to them, nor fail to profit by the curative indications which the efforts of nature point out. The minute changes so induced we pretend not wholly to explain, though many of them are readily intelligible; but the cognizable phenomena are sufficiently obvious to mark their connection and dependency, and thus to establish a rational theory of the course which nature pursues.

Relief by increased nutrient secretion not sufficing, a more general excitement seems now required, the object of which may be to call into more vigorous exercise the several excretories; and a state of generally increased or febrile action ensues. The state of irregularity is obviously the transition from the state of feebleness to that of permanently increased action or fever; and the end of the latter is to get rid of the original cause of disturbance. It is in proof of the correctness of these views that if in the stage of feebleness depletion and abstinence be resorted to, the feebleness disappears, natural vigour is renewed, and health is restored, without any febrile action being instituted; while if this state be treated with stimulants and nutritive diet, febrile or inflammatory action is sure to result. We wish here to observe that in these remarks we use the term *fever* to denote, not any of the specific diseases known by that name, but simple pyrexia, characterized by a quick pulse, hot skin, and furred tongue, being the constitutional state attendant on the ordinary phlegmasiæ, and so generally, through a radical misconception, denominated symptomatic fever. As the stage of feebleness is relievable by evacuations and abstinence, so are those of irregular action and of febrile excitement to be remedied by the same means; and if these be duly employed, any or all of these morbid conditions may be promptly corrected without specific disease or local lesion of any kind ensuing. But if they be not employed, and more especially if, through misconception, stimulants be used and nutritive diet continued, then febrile action becomes more determinately aroused, and some specific disease of an inflammatory character is engendered; or else, if the constitution be, from natural inertness or the extent of labour to be performed, unequal to the effort necessary for generating a state of fever in inflammation, the general health progressively declines, the powers of life become enfeebled, and the constitution finally sinks under some of the complicated forms of chronic disease. When, under the former of these results, active fever or inflammation occurs, it is in general speedily subjected to medical treatment; and as opinions vary but little respecting the measures to be pursued under such circumstances, while the urgency of disease requires them to be employed with proportionate vigour, it seldom happens that this stage of disease is improperly treated, at least so far as regards the use of evacuants. At this time the propriety and necessity of active treatment and of depletory practice are admitted on all sides; yet previously to the acute attack a deviation from a healthy state existed, which admitted of detection, and which as clearly indicated the propriety of some depletion, though it might not demand it so imperatively, nor require it to the same extent, as when the acute attack had supervened. Were this introductory stage relieved by adequate depletion and other suitable means, there can be little doubt that the accession of acute disease might

in every instance be averted, or at least so greatly mitigated as to be free from all danger.

It appears from all that has been stated, that incipient plethora in a healthy constitution excites at first only increased energies of healthy functions, manifested in the increased bulk and more florid aspect which such persons usually present, and in the evidences of more vigorous circulation which the pulse affords; that this state of increased healthy action, if urged too far, declines into one of diminished power, still evinced by the pulse, which then becomes low, oppressed, and irregular; and that, if these progressive changes be overlooked or unrelieved, a state of permanent excitement succeeds, such as constitutes fever or inflammation. It is obvious, then, that the increase of bulk and more florid aspect in which so many exult as evincing sound health, and which they endeavour by all the aids of good living to promote, is not a source of unmixed congratulation; but that, on the contrary, it deserves to be regarded with no slight suspicion, as actually verging on consequences by which both health and life may be forfeited. Up to this period, however, disease cannot be said to have commenced, however it may be approached; and reduction of diet, with free bowels and increase of active exercise, would suffice for getting back to sounder health without any need of medical interference. When abatement of healthful energies becomes evinced by a low and oppressed pulse, diseased actions may be said to commence, and when the stage of irregular action ensues, sensible progress may be considered as made towards the establishment of febrile action and inflammatory disease. When these latter result, medical aid and active discipline are indispensable; but up to this period much may be done by mere reduction of diet and a free state of bowels to avert the pending mischief. This condition of the body will be further illustrated, when the practical treatment required for its relief comes under discussion, the course of inquiry rendering it necessary to proceed now to the consideration of the second division of the subject, or that of relative plethora.

[An examination of the relative proportion of the constituents of the blood in plethora has shown to M. Andral, (*Hématologie Pathologique*, p. 41, Paris, 1843; or Amer. edit. by Drs. J. F. Meigs and A. Stillé, Philad. 1844,) that it differs from ordinary blood in the greater quantity of globules, and the much smaller proportion of water. In 31 specimens of blood, taken from plethoric patients, he found the mean quantity of globules to be 141; the minimum 131; and the maximum 154. His researches have led him to the conclusion, that the grand condition of the blood, which favours the production of hemorrhage, is a diminution of the fibrin as compared with the red globules. In plethora, the proportion of globules is greater than in the healthy state, whilst that of the fibrin may be normal, or below the physiological condition. When hemorrhage occurs under such circumstances, the quantity of globules diminishes, but not that of the fibrin; hence, an equilibrium is induced, and the hemorrhage may not recur, or not until an excess of globules is again produced. In scorbutic cachexia, as shown elsewhere, the quantity of fibrin is diminished, whilst that of the globules may have remained stationary. In the 31 cases, above referred to, the mean of the fibrin was 2.7;—less than the average of health; thus showing a marked difference between the condition of the blood in plethora and in inflammation.]

II. In relative plethora the earlier deviations from a healthy state take place so gradually, and the constitutional efforts are so feebly exerted, that for a long time they are nearly unnoticed. Health is observed to be less perfect; there is occasional languor and disinclination to the customary exertions, with irregular distribution of blood as marked by coldness of feet and variable countenance; the bowels are irregular, the appetite is capricious or fails, and both flesh and strength decline.

At the earlier periods of this state the pulse will be found weak, often irregular. Sooner or later a febrile or inflammatory state ensues, marked by a quickened circulation, some increase of temperature, and a white or furred tongue. This state may continue for an indefinite period, and be subject to frequent fluctuations; most frequently in course of time some part more particularly suffers, a local ailment arises which excites attention, and to which, when discovered, the constitutional indisposition is most commonly ascribed. In order to judge correctly of this condition of plethora, it is necessary to mark particularly the accordance of its phenomena with those which absolute plethora presents, especially in the changes which the pulse undergoes. This, here also, is at first feeble and oppressed, then irregular, and finally it becomes permanently quickened.

As the incipient lowness of the pulse is the symptom which so generally misleads, conveying the impression of debility, and suggesting the employment of tonic and stimulant remedies, it is highly necessary to distinguish it from a pulse of pure debility. Happily there are other circumstances besides the pulse to direct the judgment in this respect; other obvious derangements coexist, displaying a harmony of symptoms, which, taken collectively, establish beyond a doubt the existing condition of the vascular system. But the language which they speak is not always understood; their warning voice is unheeded; and the deceptive lowness of pulse is suffered to counteract the evidences which the other coexisting symptoms display. On this account it is that we dwell so much on an accurate discrimination of the indications which the pulse affords; not so much for the positive evidences which it furnishes —for there are others much less equivocal, and far more worthy of being relied on—as that, when this peculiar lowness exists, it shall not be suffered to bias the judgment or to divert the practitioner from those measures by which alone the morbid condition referred to can be corrected. A little accuracy in the mode of examination, with attention to the impressions made on the finger, will readily detect the peculiarities which we have stated; and when familiarised to the touch by habitual perception, there can be little difficulty in distinguishing them. In the condition of which we are treating, if firm pressure be made on the artery, it will be found to resist beyond what its

apparent feebleness would indicate, and, on gradually withdrawing the finger, to rebound with a force much greater than would at first be imagined. If the pressure and relaxation be a few times alternated, the sensation will be rendered more distinct. This inherent firmness is sufficiently indicative of the condition existing, and affords the best assurance of depletion being well borne. As we before stated however, and as will be hereafter more distinctly pointed out, there are other evidences to confirm what the pulse proclaims.

The state of irregularity of the pulse also requires precision in determining both its character and extent. It may be perceived as affecting both the force and frequency of the pulsations; and the irregularity of force, or that in which the artery makes a few strong pulsations, as if by a transient effort, and again relapses into a state of oppressed and diminished action, indicates, so far as we have been able to discover, a nearer approach to febrile or inflammatory excitement than the irregularity of frequency only; repeated observation of which fact has led us to infer that this stage of irregularity is the connecting link between the stages of feebleness and of permanently increased action, and that it consists of the early but yet imperfect efforts of the vascular system to form this latter stage; for when the febrile or inflammatory action is fully formed, the irregularity is no longer perceived.

The decline of power incident to a plethoric state of circulation has not been overlooked by theoretic or practical writers, however they may have failed to mark the order of succession which the phenomena present in the initiatory stage of disease, or to have deduced from these conclusions capable of affording practical guidance. Dr. Gregory, who has faithfully represented the state of physiological and pathological science as they existed when he wrote, notices distinctly both the weakness of the circulating organs and the inordinate burden imposed on them by a state of plethora. "Multa mala à nimia plenitudine oriuntur. Homo nonnunquam fere opprimitur, hebes, languidus, debilis fit, neque ipsa quæ sanguinem movent organa ad tantum onus impellendum valent. Pulsus languet, et aliquando syncope, et vertigo, et palpitatio observantur. Sæpius vero vasa nimis distenta, ad motus præter solitum vehementes et abnormes proclivia fiunt." Here the facts are explicitly stated, but the connection of the state of debility with that of increased action is not traced, while symptoms, which belong to more advanced periods of disease, and arise from ulterior derangements, are intermixed, creating confusion. And, further, the stage of permanent excitement is regarded rather as the result of over-distension of vessels, than of the stimulus of redundant nutritive matter over-exciting the vital powers.

As the succession of these several stages may be observed taking place naturally, so may the changes be accelerated and displayed by means of medical treatment; for if the constitution be long oppressed, and have long endured the stages of feebleness and irregularity, moderate depletion has the effect of relieving the vital powers, so as to bring on the period of increased action much sooner than it would otherwise occur. This effect is strikingly exemplified by Dr. Watt in his valuable treatise on diabetes; in which he has shown that the pulse may be raised from the extreme of depression to vigorous action by free bloodletting, and that under this process the blood itself becomes changed from a dark grumous mass, scarcely coagulating, to the blood of active inflammation, with firm coagulum and thick buff. Changes similar to those recorded by Dr. Watt we have had repeated occasion to witness both in diabetes and in cases where no urinary affection existed; and for many years we have been accustomed to refer them to the pathological state of the vascular system which we are now endeavouring to explain. This state also will require further illustration when its practical treatment comes to be considered; but ere we pursue the subject of nutritive plethora further, it is necessary to notice the vitiation to which the blood is liable from its becoming overcharged with the excrementitious matter carried back to it by the absorbents, which in the ordinary course of health ought to be regularly expelled, but which, under impaired energies or interrupted functions of the excretory organs, accumulates in the blood, oftentimes to a considerable extent, vitiating its quality, unfitting it for healthful nutrition, and oppressing and debilitating all the powers of life. The necessity for noticing this state arises from its being continually combined in various proportions with the condition of relative plethora, the progress of which it sensibly impedes, and the phenomena of which it complicates and obscures.

III. In the morbid condition which we are now to notice, the deviation from health takes place still more gradually than in relative plethora. Indeed, so insidious is its advance, that, not producing any immediate or special disease, and marked only by change of aspect and some abatement of wonted powers, it is for the most part overlooked, or at least undergoes no adequate investigation. Combined as it is, too, with relative plethora in every proportion, and by its debilitating effects even ministering to this latter, it becomes confounded with derangements of a character essentially different, and the influence which it exerts both in generating and modifying disease, fails to be recognised. It arises from defective excretion; and as exercise is the natural stimulant for exciting the various excretions to an adequate performance of their functions, this condition more peculiarly occurs in the sedentary and the indolent. It is characterized by great sallowness of aspect and duskiness of skin; the pulse is low and compressible; the surface of the body is in general harsh, dry, and deficient in natural transpiration; the tongue is for the most part moist and clean; the appetite capricious, often voracious; the alvine evacuations are inveterately foul, exhibiting no traces of healthy secretion; the urine is high-coloured, depositing a dark sediment, and often very fetid; even the perspiration has frequently an offensive odour, and gives a dusky tinge to the linen which absorbs it. The state here described has not escaped observation, having been noticed by medical writers, and even ascribed by them to the causes here assigned. Ramazzini more than a century ago represented distinctly this condition of body, as induced in

certain artificers by sedentary habits and inactive life, explicitly referring the sallowness of aspect and depraved health, together with certain defœdations of the skin, to the *excrementitious* matter of the body being imperfectly discharged. In his work, "De Morbis Artificum," ch. xxx. he remarks, "Scabiosi quoque decolores, ac mali habitus esse solent sedentarii artifices, sarcinatores potissimum, ac mulieres quæ suis in laribus die ac nocte, ut victum sibi quæritent, acu operantur, hæ enim mala inexercitatos comitantur; nam vitium capit sanguis ni moveatur corpus, *unde illius excrementa in cute restitant, et universus corporis habitus vitiatur.*" Again he states, "Mala igatur intemperie et multa vitiosorum succorum redundantia laborare solent hujus modi artifices, ob vitam sellulariam quam degunt, ac præsertim sutores. Non sic tamen multi alii artifices qui sedendo operantur, uti figuli, textores, qui brachia et pedes, totumque corpus exercent ac propterea saniores sunt, ut *quibus sanguinis impuritates facilius per hujusmodi motum discutiantur.*" Here are represented as distinctly as words can convey, both the accumulation of excrementitious matter resulting from inactivity and defective excretion, and the depravation of habit to which such redundancy gives rise.

The manifestations now noticed as belonging to excrementitious redundancy are intermixed in every proportion with those of relative plethora, the two conditions mutually reacting on each other. Arising, however, as they do from totally different sources, it is highly necessary to discriminate them so as to impute to each what belongs to it, and thus render the practical treatment more definite and precise. No symptom marks the existence of excrementitious excess in the blood more signally than the obstinate foulness of bowels so often encountered in various maladies, and which no employment of purgatives seems to correct. If by their use such relief be given to the system as empowers it to make a febrile or inflammatory effort for impelling blood into the capillaries, renewing more active processes of secretion, and thus ministering to its own relief; if the pulse become quicker and firmer, the tongue white and loaded, with such evidences of increased activity of circulation as to warrant the use of small bleedings, these, if employed with sound discretion, and adapted to the powers of the constitution, will, in conjunction with the excited powers with which they are used to co-operate, do more to correct the morbid condition of the bowels, and thus restore healthy evacuations, than any use of purgatives however judiciously managed or perseveringly employed. This fact we have so often witnessed, that when this state of bowels is found to resist purgative treatment, we have for many years been accustomed to resort to the moderate use of the lancet, as the most effectual auxiliary of purgatives that can be employed. Bloodletting, however, in this morbid condition of the system, requires much caution and a clear conception of the principles on which its employment is founded, to guide its use; for if resorted to at too early a period, while the powers of life are still torpid and inert, or if pushed even a little beyond what those powers can bear, much mischief and formidable exhaustion may result. Some tendency to renewed excitement ought perhaps to be manifested ere the lancet be used; but when this presents, then small bleedings will contribute to rally the dormant powers far more effectually than the most potent tonics.

In the transition here noticed of the sluggishness of system belonging to a state of excrementitious redundancy, into the excited power manifested by febrile action, it cannot fail to be observed how closely the latter corresponds with what has already been described as occurring in relative plethora. In fact, so far as the state of excitement is concerned, the conditions are identical, displaying the same pathological phenomena, and ministering to the same end, the only difference being the modification which any great degree of excrementitious accumulation produces in the actions and symptoms; which after all is a difference more in degree than in kind; for when relative plethora has existed for any time, excrementitious accumulation is sure to become combined, it being the direct product of the debility and imperfect excretion incident to this morbid condition.

The consideration of excrementitious redundancy might with propriety have been included in that of relative plethora, were it not that the separate notice of it renders its nature and phenomena more clear and explicit. For practical purposes, however, the two states cannot in our conceptions of them be disunited, for relative plethora gives rise to excrementitious redundancy; and when any high degree of the latter primarily occurs, it is most probably incapable of correction without the intervention of those sanative efforts which the constitution itself makes when aroused into febrile excitement. To promote these efforts, not merely by exciting enfeebled powers with stimulants, as is too much practised, but by diminishing their labour, and thus rendering them more adequate to its performance, through the cautious abstraction of blood, and the establishment of more efficient excretions, is the process by which the objects of the medical practitioner will, in numberless instances, be best attained. To pursue this course, however, requires unbending integrity on the part of the practitioner, and firm confidence on that of the patient. It is opposed by many prejudices; it works not like a charm, and extravagant expectations of instantaneous results would not be realized. Time is required for its success; it is nature that effects the cure, and her operations are not to be hurried. They, however, who are willing to abide by her slow but sure exertions, and who value the re-establishment of perfect health more than the temporary alleviation of some partial ill, will be amply repaid in the fulfilment of their more rational desire, so far as it is attainable by human means; and we can confidently say, from the experience of a life which has for above thirty years been devoted to medical science and practice, that the satisfaction which we have derived from witnessing the renovation of health and strength thus effected, has surpassed even that which the signal relief of acute disease by active treatment, and the consequent saving of life, has ever afforded.

Treatment. — We proceed now to consider the practical treatment of the three several conditions to which we have directed attention, namely,

absolute plethora, relative plethora, and excrementitious redundancy.

1. *Absolute plethora.*—In this condition, including the diseases to which it gives rise, we may tracc three progressive stages. The first embraces the period which precedes febrile or inflammatory excitement; in the second, febrile excitement exists unaccompanied by any prominent local affection; and in the third is superadded some local inflammation, or other partial derangement, constituting what is usually deemed a specific disease. When the latter arises, it no doubt reacts on the constitution, aggravating the several disturbances in proportion to the importance and the degree of derangement of the organ or function specially affected. But if the series of morbid actions here represented be that which nature follows, it is clear that they are much in error who ascribe what is miscalled sympathetic fever to the local disease coexisting, which, instead of exciting the attendant fever, is only its direct product.

The phenomena which mark the incipient stage have been already noticed and explained; and it was stated generally that the proper treatment for correcting this morbid condition consisted essentially of depletion to remove the plethora, and abstincnce to prevent its recurrence. And this treatment, if timely employcd, would always suffice. Indeed, in the very early periods, abstinence alone would, by cutting off the supply of inordinate nutriment, give effectual though slower relief. But were this otherwise, inasmuch as they who become so affected are still considered as enjoying perfect health, it would be useless to lay down rules of treatmcnt to which none would be likely to resort or conform. Indeed, we should be reluctant to lay stress on this initiatory stage, if doing so were to induce any suspicion of a wish to bring under medical discipline those who probably exult in their not requiring its unenviable interference. Even if it werc in our power, therefore, to arouse every such individual to a full sense of his approximation to disease, and of the dangers to which this exposes him, we should hesitate to give rise to such incalculable misery as a perpetual watchfulness over the feelings of health could not fail to occasion; for though many might, by timely precaution, avert diseases that would otherwise ensue, the constant anxiety to which numbers would be unnecessarily consigned by the prevalencc of such impressions, however correct, would greatly counterbalance any good that could result. It is of consequence, however, that medical men should have a just conception of this state when subjected to their obscrvation, so as not to be misled by delusive appearances; and it is of the highest importance, whcn, as continually happens, acute and dangcrous maladies have a tendency to return, to be aware of the premonitory signs that mark an approaching accession, so as to employ in time the means necessary for averting its recurrence. To precautions of this kind, as formerly mentioncd, the writer was indebted many years ago for his own preservation and re-establishment of health; since which period he has had ample opportunity of proving, by extensive application of the principles now inculcated, the value and efficacy of such timely prevention.

When the stage of disease now under consideration is subjected to medical treatment, the means of relieving it are simple in the extreme, consisting only of moderate bloodletting, occasional purging, and reduced diet, with a speedy return to such exercisc as may be required for keeping the several secretory and excretory organs in the adequate and healthful discharge of their functions. By these means, pursued without any sensible impression on the general strength, and scarcely an interruption of ordinary avocations, may this condition be effectually relieved, and the dangers to which it leads successfully averted. It may conduce to accuracy of conception to explain here what is meant by *moderate bloodletting*. The object is to remove a certain portion of the circulating fluid in order to diminish the proportion which the nutrient matter bears to the watery solvent. This latter is so readily absorbed and carried into the circulation, that the actual volume of the blood becomes speedily restored. For the relief of incipient plethora it will in general suffice to abstract twelve or sixteen ounces of blood at a time, the evacuation being repeated as circumstances may require, both the amount and the repetitions being dependent on the individual constitution. In the case of the writer, when suffering under this stage of plethora, much larger depletion was required; above thirty ounces being often taken from the arm without the evacuation being otherwise felt than in the relief which it afforded. If the necessary relief happencd to be postponed, so as to approach the period of active fever, the bloodletting required to be of still larger amount. At such time there was gcnerally some uneasy sensation, caused by certain local determinations of blood to which the writer was subject; and when this existed, blood was usually suffered to flow without regard to quantity, until the uneasiness subsided. If the evacuation stopped short of this effect, the relief was incomplete, and a speedy repetition of venesection was sure to be required, and to a greater amount. From this free use of the lancet, guided as it was by a definitc purpose, and bounded by certain limits, though these were not measured by quantity, the writer never in any instance suffered injury such as is so often ascribed to large bleedings, and he is quite satisfied that by observing the rule which has been stated, more effectual relief was obtained, and that morbid actions were restrained with less ultimate loss of blood, and less prostration of general powers, than if blood had in the first instance been sparingly taken.

The principle of carrying bloodletting to the extent of making some impression on the constitution, and thus arresting the progress of morbid action, we shall have to consider more fully when we come to treat of its employment in active inflammation. We may here, however, cursorily remark, that when morbid actions of an inflammatory kind prevail to such extent as to demand direct depletion by bloodletting, effectual relief is not afforded unless the sufficiency of the depletion is manifested by some impression on the vital powers; for under high and active inflammation, twenty, thirty, forty, ounces or more, may be abstracted without making any impression, when the

loss of a few ounces more will, by inducing a disposition to syncope, at length arrest completely the inflammatory action, and repress the violence of disease. In such case, if the depletion be regulated by regard to the quantity of the blood taken rather than the effects resulting; and if from vague apprehension of injury it stop short of that relief which ought alone to set limits to it, the morbid action is left unsubdued, and much greater loss of blood is required eventually to allay it; and this with considerable risk of its then failing to accomplish its end; for independently of the hazard of allowing inflammation to continue in any organ essential to life, it should ever be borne in mind that in proportion to the time during which morbid action of this kind is suffered to continue unrestrained, will be the difficulty of finally subduing it; and consequently, that whenever active inflammation arises, it can never be too soon nor too effectually arrested.

From ample experience of the correctness of these views, we have long been convinced that when active inflammation occurs in a robust and vigorous frame, copious depletion in the earlier stages is the surest means of saving animal power and of accelerating perfect recovery. In the initiatory stage of plethora, however, such active measures are not needed. The object here is to reduce the quantity of blood as the most direct means of altering its quality; there is no inordinate action to subdue; and however moderate the depletion, it must give relief proportionate to its extent, the ground gained being afterwards maintained by other evacuations and abstinence. But when, from continued or increasing plethora, the second stage, or that of febrile action ensues, then the principle which we have noticed becomes directly applicable. When the oppressed pulse passes into a state of irregularity, and thence into one of permanently excited action, as manifested by a quickened circulation, hot skin, and white tongue, active depletion becomes necessary, and it requires to be regulated on the principle now stated. At this time, too, other auxiliary remedies are needed. Of these purging is the most direct and most powerful, and saline purges, which produce copious watery discharges from the bowels, are among the most effectual. Several neutral salts and antimonial preparations are also valuable, as co-operating in the general purpose by the increased secretions to which they incite the kidneys and skin; and by the judicious administration of these several remedies in conjunction with low diet, may this second stage in general be promptly and effectually relieved. The mode of exhibiting these remedies is so familiarly known and so continually practised in the treatment of the several phlegmasiæ, which so much prevail, that it would be superfluous here to enter into further details.

When local inflammation becomes superadded to the febrile excitement, we have then to consider not only the general plethora and febrile condition of the system, but also the state of the organ or part locally affected. If it be an organ essential to life, then the utmost activity of practice is required to guard against the danger arising from its functions being suspended or impeded, and from the disorganization of structure which continued inflammation is sure to induce.

It would exceed our province to notice here every local inflammation with which a predisposed body is liable to be assailed. For the purpose of illustration, therefore, we shall confine our remarks to two of the more urgent, and, by particularizing the treatment which they require, exhibit the principles of practice so clearly as to render them easily applicable to every corresponding case that can occur. With this intent we shall select two organs of primary importance, the brain and the lungs. When active inflammation of either organ is manifested by its appropriate symptoms, the necessary treatment must be promptly and vigorously applied, for the danger arising from suspended or impeded function is considerable, and both the obstinacy and danger are enhanced in proportion to the delay of the necessary depletion, and the insufficiency of its early employment. If bloodletting be not early and vigorously employed, such derangement of structure may quickly ensue as to destroy life, or permanently unfit the organ for the discharge of its ordinary functions. The effect of bloodletting in this case is twofold; by the quantity of blood abstracted it diminishes plethora, and by its influence on the moving powers it moderates or subdues the arterial actions by which inflammation is upheld. As inflammatory action in such cases cannot be too soon arrested, and as suddenness of depletion greatly promotes its speedy effect on the moving powers, the blood should be taken from a large orifice, in a full stream, and with the body erect. To be effectual, the depletion should be carried to the extent of making sensible impressions on the local symptoms of either head or chest, and this will be found to coincide almost uniformly with abated action of the artery as felt at the wrist. When under the flow of blood the pulse falters, the lips become pale, and the face bedewed with perspiration, bloodletting may be confidently relied on for yielding all the relief which this truly potent remedy is capable of affording. The quantity necessary to produce this effect varies greatly. The writer has himself lost from forty to fifty ounces at one bleeding, and has nevertheless required a repetition to smaller amount within a few hours. We have known much larger bleedings employed in urgent disease with only salutary effect and without a single bad consequence resulting. As cases of extreme violence are those in which inadequate depletion would prove most fatal, it is necessary to notice the amount to which bloodletting may under urgent necessity be safely carried. Happily such cases are not the most frequent, and in the more moderate instances which most prevail, evacuations much more moderate will suffice. When by one or two bleedings, so conducted as to make impression on the moving powers, the more urgent symptoms are alleviated, the repetitions may then be regulated so as to keep within the bounds of all possible risk of excess.

If the plethora be considerable and the fever continue high, it may still, even though the local symptoms have yielded, be requisite to take more blood, so as to bring back the circulation to a

healthy standard, and subdue remaining excitement, or relapse of inflammation may occur. By such means, combined with the auxiliary remedies already noticed, and assisted by the topical treatment suited to each local disease, a state of the most imminent danger may be speedily changed to one of perfect safety, provided organic lesion has not yet taken place.

The practice here inculcated may possibly appear to some bold and hazardous, but we can confidently appeal to the experience of those whose opportunities of treating active inflammation have been greatest, for the soundness of the principles which we advance, and for the perfect safety of the measures enjoined. We willingly admit that the ordinary course of medical practice may be carried on by less active treatment, for a large proportion of ordinary cases requires no more; but when urgent disease occurs, the attempt to dispense with proportionate activity of treatment can lead only to fatal results or tediously protracted disease. We have purposely dwelt on the severe rather than on the milder instances, in order to show more clearly and forcibly what the principles are on which the treatment should be conducted. As the symptoms of each case, and the constitution to be acted on, denote the activity required, and thus guide the practitioner in the use of his remedies, there can be little hazard of the representations here made misleading any one into a rash or excessive use of bloodletting.

It may not be amiss here to take notice of two consequences, either of which may attend a very full bloodletting, namely, syncope and convulsion. They are prone to occur when much blood is taken, and especially when the patient is bled in an erect posture. There seems little room to doubt that both arise from the vessels of the brain being too much emptied, the enfeebled action of the heart being insufficient to refill them; and, as is familiarly known, recumbency of the body, which allows the blood to return to the brain with less of the heart's impulse, is the direct, and, we may add, uniformly effectual remedy. It has happened that patients bled to syncope have not revived; but this has been of rare occurrence, and when it has taken place, we should strongly suspect that blood must have been drawn beyond all prudent bounds, or that the propriety of taking any blood was questionable. We have witnessed many instances both of syncope and of convulsion, and can truly affirm that we never saw a single case in which injury of any kind resulted. We are no advocates, however, for bleeding syncope, and never direct it, although, if urgent disease were to be arrested, we would go to the verge of it, for the reasons already assigned. Convulsion is an effect more formidable in appearance than syncope; and yet, though we have frequently seen it so induced, we have never known harm attend it. In its effect of lowering arterial action, we regard it as perfectly analogous to syncope, and for all that we have seen, equally innocuous. Yet, as it is always alarming to the bystanders, and as neither it nor syncope is necessary to ensure the full effect of bloodletting in subduing inflammation, we would willingly avoid both. There is a caution which we here wish to suggest to those who may have occasion to draw blood largely, namely, never to leave a patient so depleted until placed in a recumbent posture. The following case, of recent occurrence, will illustrate what we mean. We were requested to visit a man who had been seized with apoplexy some hours before. We found that he had been promptly bled, and to a large amount. The quantity of blood which we saw could not be under seventy ounces; it was thickly buffed in the earlier drawn portions, and we saw no reason to doubt the propriety of its abstraction. Having bled the patient, the medical attendant, pressed by other engagements, went away directing him to be placed in bed as soon as possible. Circumstances prevented this being done, and when we arrived he was still sitting in the chair in which he was bled, held there by four stout men, whose united efforts were required to restrain the horrible convulsions which recurred every quarter of an hour or twenty minutes: he had been in that state for nearly two hours! His countenance was ghastly, the eyes glassy, lips livid, and breathing irregularly laborious. We had him instantly laid on the ground, and as speedily as possible transferred to bed; nothing more was required, for circulation soon returned, the pulse again became distinct, the countenance calm, with returning colour to the lips, and the breathing tranquil. This was an extreme case, being by far the worst we had ever witnessed. The bloodletting was unusually large, and severe convulsions continued at intervals for nearly two hours, owing to the imprudent continuance of the erect posture. Yet so little injury did this man suffer, that in less than ten days he walked to his physician's house, free from complaint, to thank him for having visited him.

It should be recollected that in the practical remarks hitherto offered, we have had in view inflammatory complaints only as they occur in absolute plethora, consequently in their most active and violent degree. In this state they require large depletion, and there is always ample power to sustain it, the danger being that of falling short of the quantity necessary rather than of exceeding it. Diseases of the same species, however, occur in every condition of the system, and according as they take place in feebler constitutions, and are marked by less violence of symptoms, may measures of less energy be trusted to for their relief. It is from not noticing the difference of constitution or the degree of general plethora present under attacks of local inflammation, that so much diversity of opinion has prevailed among medical practitioners respecting the extent of depletion required. From peculiarities of local districts, some practitioners never encounter diseases of this violence. They accordingly find that copious depletion may be dispensed with; that if employed, it sinks the powers of life, and lessens the chances of recovery, and thence they somewhat hastily conclude that the active treatment pursued by others is rash and unnecessary. Diseases of this languid character may be supposed to prevail most in large and crowded cities, where the habits of life are sedentary and luxurious, and where inflammatory complaints are connected more with relative plethora than with absolute. Perhaps London may be taken as the best exemplification

of this remark; and it is very generally believed that there the corresponding diseases do not bear the activity of treatment which the provincial practitioners find indispensable. We have it asserted, however, from high authority, that this is a misconception, and that no such difference exists, at least to the degree represented; for that London citizens both require bleeding as freely and bear it as well as the residents of any other district. The subject, however, will come more appropriately into the next section.

2. *Relative plethora.*—This variety being of more frequent occurrence than absolute plethora, and having connected with it a greater number of diseases, the consideration of it is still more important, and entitled to closer attention. In it, too, the progress of morbid action is more gradual, and the constitutional efforts to rectify existing derangements are more varied and more general. Hence the character of the disease produced by or incidental to this condition is complicated, and their elucidation proportionally difficult.

The earlier phenomena being less conspicuous, attract less attention, and the equivocal character which they frequently present being liable to misconception, it becomes important to illustrate clearly the real nature of this condition, to exhibit distinctly the phenomena which characterize it, and to point out accurately the practical treatment suited to its relief, in order to prevent the highly injurious practical errors, to which misconception in this respect so continually gives rise.

In relative plethora, as in absolute, the earliest deviation from health is marked by evidences of diminished power in the general circulation. The pulse becomes low and oppressed, and the general powers enfeebled. When, from natural feebleness of constitution, or the absence of excitement, this incipient stage is prolonged for any considerable time, the impaired energies and deficient exercise of the several excretory functions give rise to more or less of excrementitious accumulation, and a combination of these opposite conditions results. More frequently, however, this stage passes into that of increased action, and some congestion, inflammation, or other local malady becomes manifested. A hard and frequent pulse, increased heat of skin, and whiteness of tongue, mark the formation of the second stage; and if in moderate degree, and unexasperated by stimulants, this may, in constitutions not predisposed to any particular malady or local lesion, continue for months or even years without any specific disease ensuing, and with only progressive deterioration of general health. We have so often met with this state clearly characterized, that we have been in the habit of distinguishing it by the term *constitutional inflammation*, meaning thereby to designate general inflammatory action in the system, unattended by local inflammation.

All the phenomena which belong to this stage are of an inflammatory character. Blood drawn frequently exhibits a thick, buffy coat, with cupped and with contracted edges, and the treatment of inflammation is that which alone affords effectual relief. If taken at an early period, moderate depletion and antiphlogistic regimen will speedily correct it; but if neglected or improperly treated by tonics and stimulants for any length of time, it becomes more difficult to remove, acquiring obstinacy from its continuance, and through the congestions and local determinations which are prone to occur during its progress, laying the foundation of various specific diseases of the worst kind. The treatment of the several stages requires to be discussed at some length, and copiously illustrated.

Absolute plethora in its simplest form and earliest stage may be relieved by artificial means, without any excitement of the system being necessary to co-operate in the restoration of health. This the writer has unequivocally experienced in his own person, and he has thus been enabled to satisfy himself of a fact which is not often subjected to medical observation. In relative plethora it is questionable whether the capillary congestions, and other derangements of minute structure and function attendant on this condition, be removable without some sensible effort of the constitution, and whether febrile excitement, in some degree, be not a necessary agent in effecting a recovery. That it is often contributory to this end, we entertain no doubt. These observations have direct relation to the practice suited to the several stages. Should the earlier of these, in consequence of the decline of health to which its long continuance gives rise, come under medical cognizance, sparing depletion to lessen the redundancy, with moderate excitement to arouse the energies of the system, will be the most judicious and suitable treatment. Under extreme feebleness of pulse and great muscular debility, it may be prudent to commence with gentle excitement, watching carefully the time when increased action in the pulse manifests that renewed energy which will both justify and bear direct repletion. We are certain, from much observation, that when the pulse becomes irregular, blood may be taken, not only with safety but advantage, and that the relief afforded will be speedily manifested by the increased fulness and tone which the pulse acquires. For this purpose the earlier bleedings should be small; from four to six ounces may suffice to commence with. The repetitions will of course depend on the effects, and it is a subject of interest inferior to none which pathology presents, to mark in the extreme cases of such condition how progressively, under repeated venesection, the pulse rises, and the buffy coat is displayed on the blood. Some striking instances of this we have recorded in another place. In an enfeebled and emaciated boy, labouring under diabetes, 209 ounces of blood were drawn in twelve successive bleedings, the blood becoming changed from a dark grumous coagulum of loose texture to the thickest and firmest buff; and the strength of the body increased from feebleness hardly admitting of an erect posture, to a degree of vigour which enabled him to hold the plough for several hours a day. It may afford a clearer conception of this condition, and show the ability which the body acquires through bloodletting of bearing copious depletion, to present here a tabular view of the successive venesections practised in this case, with their amount, intervals, and the character of the blood drawn:

No.	Date.	Amount.	Quality of blood.	Total amt. at each period.
1,	Nov. 6,	12 oz.		12 oz.
2,	" 7,	14 "		26 "
3,	" 9,	17 "		43 "
4,	" 11,	14 "		57 "
5,	" 15,	17 "	buffy,	74 "
6,	" 18,	20 "		94 "
7,	" 20,	20 "		114 "
8,	" 25,	18 "		132 "
9,	" 27,	18 "		150 "
10,	Dec. 13,	20 "		170 "
11,	" 20,	17 "		187 "
12,	" 29,	22 "	buffy,	209 "

In another case, of a weakly and delicate female, without any special disease or local ailment, save pains irregularly alternating in the head and chest, 106 ounces were taken at seven bleedings, with similar changes of blood, and as well-marked improvement of general strength. Such instances may be deemed conclusive of the fact that the state of constitution which we are endeavouring to illustrate has a real existence. In these cases, the early symptoms were those of seeming debility; yet if this had been such as is generally imagined, life must have been inevitably destroyed by the means employed. If, then, there are states of disease marked by considerable debility, in which the constitution not only bears depletion without sinking, but acquires very considerable accession of strength under copious evacuations, it surely must be of the first importance to medical science to scrutinize such conditions of the system, and acquire juster notions of its real nature than are generally entertained.

When, by the judicious combination of small bleedings and moderate excitement, assisted by other evacuations, the system is aroused to greater energy, and a state of febrile excitement ensues, the treatment of this must be conducted on principles with which all are familiar. When a hot skin, quick pulse, and furred tongue present, no practitioner is deceived, or fails to resort to proper remedies. Our great object is to direct attention to the earlier and more obscure stages, to show their connection with the febrile state, and to demonstrate the correspondence which prevails in the treatment which they respectively require. The earlier the advance of such disease can be detected, the less will the interposition of art be needed, and the more effectual will it prove, both in correcting the febrile state, and averting the local injuries which continued febrile action will always sooner or later induce. There are occasions when this vigilance in detecting the incipient deviations from health is of the very first importance; a signal instance of which we shall briefly notice, as illustrating what it is wished to impress, and as proving the soundness of the principles by the efficacy of the treatment which they dictated, perfect recovery having taken place under circumstances which seemed to augur a very different result. A young woman applied to the writer above three years ago, with ovarian tumour, accompanied with great inflammatory action, both local and constitutional. Active treatment was employed, and the progress of the disease arrested. Continued attention, however, was required to keep down inflammation, and both bleeding from the arm and cupping were in constant requisition. Auxiliary means were freely employed, but bloodletting was the remedy which gave most decisive relief. So sensible was she of the advantage, and so intelligent in noting the premonitory indications which marked the necessity of depletion, that she was accustomed to ask for the lancet or cupping-glass, specifying her reasons for thinking they were needed; and on these occasions she was invariably right. To detail minutely a case which was subject to medical discipline for so long a time, would be tedious and unsuited to our present purpose. It may suffice to say that the constitutional state tended throughout to inflammatory action, and that by the fluctuations of this the local disease was influenced. The tumour advanced so as to form a considerable prominence in the right hypogastrium. Cupping, leeching, blistering, were all employed, and eventually a caustic issue was established over it. So much relief was obtained, that she was occasionally discharged from the hospital, in order to recruit her general health. After a short absence, however, she was sure to return with renewed disease, both local and general. It being sufficiently manifest that the local excitement was always preceded by febrile action, the propriety of looking closely after the latter was apparent. If fever was not speedily arrested, the tumour became active and increased; when, by early bloodletting, febrile action was reduced, the tumour remained quiescent. Early bleeding was therefore the remedy most worthy of reliance, and it was resorted to accordingly, with due caution, but determined perseverance. And here we were happily assisted by one well-marked evidence of renewed plethora and approaching fever that never deceived us. Ere pain was felt in the seat of disease, or any of the ordinary indications of fever presented, a dark narrow dry stripe appeared on the centre of the tongue. If this were unheeded, it soon expanded at the tip, and spread slowly towards the edges. By a moderate bleeding, this was promptly removed, and its sure attendants, general fever and local pain, were averted. By steady perseverance in the treatment here noticed, all disease was eventually removed; and within these few days we have seen this person in perfect health, and without a vestige of tumour remaining. We have no hesitation in attributing the fortunate result to bloodletting, and also to this being regulated on the principles which it is the object of this essay to inculcate. We may add that it never required to be carried to the extent of making even a temporary injurious impression on the general powers of the constitution.

We have stated that the state of febrile excitement is preceded by certain changes in the pulse indicative of its approach, and also that we are not under the necessity of judging solely from this evidence, for that other derangements coexist, which evince a harmony of symptoms, and that the whole collectively furnish indisputable proof of the actual condition of the vascular system. On the peculiarities of pulse we are not anxious to dwell, further than to give a seasonable warning that they be not suffered to bias the judgment through fears of an unreal debility. In judging

of the approach of febrile excitement, we are accustomed to rely more on the state of the tongue than on that of the pulse. When the constitution is assuming a disposition to febrile excitement, ere this is announced by the pulse, still feeble and compressible, the tongue presents a peculiar whiteness strongly characteristic and expressive, being distinct from any apparent secretion, and obviously resulting from some defect of capillary circulation in the tongue itself. This whiteness we have often seen disappear under bloodletting ere the arm was tied up. To describe it more particularly would be useless; to be known it must be seen, and they who are accustomed to inspect inflammatory tongues will at once recognise the condition to which we allude. We know not a stronger or surer evidence of incipient febrile excitement than this appearance of the tongue presents, and when it exists we should consider some abstraction of blood both justifiable and necessary. It appears, then, that bloodletting is suited to each stage of relative plethora. In the stage of feebleness when long protracted, small evacuations of blood relieve the oppressed constitution, thus enabling it to form the stage of febrile excitement which seems so necessary an agent in correcting the several derangements of the system. When used for this purpose, the early depletions should never be large, from four to six ounces being oftentimes as much as can with propriety be taken. According as febrile excitement advances, more copious depletion will not only be borne but required. The object of the incipient bleedings is not to make that impression on the moving powers which is necessary for the abatement of inflammatory action, but merely to abstract a portion of the circulating fluid, and thus lessen the plethora by which the system is oppressed. The blood may therefore be taken from a small orifice and in a recumbent posture. According as the period of excitement approaches, the effect of depletion in hastening its advancement becomes more manifest; and indeed it is a matter of familiar observation to surgeons, that even while the blood yet flows from the vein, the arterial powers so sensibly increase that the tardy and sluggish stream, which at first only trickled down the arm, becomes converted into a full and vigorous jet, the blood being oftentimes propelled to a distance of several feet. When this degree of increased action is displayed, blood may be more freely taken, and antiphlogistic treatment more rigorously pursued.

During the advanced stage, the object of venesection is both to abstract blood and to moderate inflammatory action by the direct impression which this remedy makes on the arterial system. Wholly or suddenly to subdue this action is not here intended, unless there be also local inflammation of a hazardous kind. The abstraction of eight or ten ounces will often suffice; that of twelve, sixteen, or even twenty will very frequently be well borne.

When local inflammation is superadded, then the extent and frequency of bloodletting must depend on the urgency of symptoms present, the importance of the organ principally affected, and the danger of this sustaining injury such as would be either immediately fatal to life, or ultimately subversive of health and vigour. Though in this state of constitution bloodletting is the remedy most essential, and which most effectually arouses the sanative energies of the system, yet other means are required for co-operating in the general purpose, and for re-establishing the several functions of life in their healthful and efficient exercise.

Next in power to bloodletting as an evacuant is purging, and this requires to be employed with much discrimination, if the full benefits of it are to be obtained. The objects of it here are both to deplete the system, and to restore to healthful efficiency the excretory processes connected with the alimentary canal, which, in the early stages of relative plethora, are always inadequately performed. Simple as the process seems to be by which the bowels are evacuated, we scarcely know a term in medicine more vaguely employed than that of purging. It is continually used to express processes essentially different, and which require to be accurately distinguished from each other. By observing closely the effects of different purgatives and the nature of the discharges produced by them, we may perceive some well-marked differences in their modes of operation. Those of one class simply evacuate the feculent contents of the bowels; those of another excite the various exhalant arteries, producing watery stools; and those of a third stimulate the mucous follicles which so abundantly line the intestines, causing them to throw off the mucus which they so copiously secrete. When the bowels are merely inactive, their secretions healthy, and no constitutional disease present, the simple aperients of the first class suffice to obviate costiveness and prevent feculent accumulations. Medicines of the second class are indicated, when, besides unloading the intestines, it is expedient to abate arterial action, or allay fever by abstracting fluids from the system. Those of the third are required when mucus, inordinately secreted, accumulates so as to clog and obstruct the secretory vessels themselves, and also when this accumulated mucus, acting as a foreign body, becomes instrumental in exciting or aggravating disease. The particular medicines belonging to each class will readily present themselves to every practitioner, and need not here be specified; neither is it important to distinguish them by any very accurate arrangement. The same medicines will act differently on different habits and under different circumstances, and it is the effect, not the medicine producing it, that is the chief object of consideration. On the simple aperients we have little to remark; they form a most useful class of remedies, and may be combined with the second and third classes, so as to assist in producing every species of alvine discharge. The several aperient neutral salts are well known as the principal purgatives for producing watery stools. When increased discharges of mucous secretions are required, our chief reliance is on certain preparations of mercury and of antimony. The stomach, forming part of the alimentary canal, requires itself to be occasionally unloaded, which is effected by emetics. And here too we should distinguish between those emetics which simply discharge the floating contents of the stomach, and those which cause it to throw off increased mucous secretions. Even though

vomiting be not resorted to, the mucous secretions of the stomach may yet be expelled by combining with purgatives such preparations of antimony as have an emetic operation. Consistently with these views it would appear that the most perfect evacuation of the whole canal must be that procured by combining medicines of each class, and accordingly we find the purgatives in most general use so constituted. When full purging is required to allay fever or lessen arterial action, no practice is more common than to give at night a suitable dose of extract of colocynth or of aloes, which are simple aperients, combined with calomel and antimony, medicines that expel mucous secretions, and followed next morning by a saline purgative, which, while it accelerates the operation of the previous dose, produces also copious watery stools. When these latter are not required, but yet a state of disordered intestinal secretion is manifested, it is often expedient to correct this latter gradually, the nature and activity of the cathartic employed being suited to the particular design; and whether it consist of colocynth, calomel, and antimony, or of rhubarb, blue pill, and ipecacuan, the same principles govern its administration, and similar effects, differing only in degree, are produced. With these principles to guide the employment of purgative remedies, they may be so administered as to prove most powerful auxiliaries of bloodletting in the several stages of relative plethora. In the earlier stage, simple aperients, combined with mild doses of mercury and antimony, are the most suitable. According as the febrile stage succeeds, saline purges may be more freely employed; and when fever becomes active, or local inflammations arise, these are indispensable. In proportion as the mucous secretions are accumulated or depraved—and they become signally so whenever the earlier stage of relative plethora has been of long duration—then must those combinations be employed which most effectually deterge the loaded membrane, and restore the secreting vessels to their natural condition.

A consideration of the several changes that take place in the body under febrile excitement, and a more minute observation of the immediate effects produced by increased arterial action on the several secretory and excretory organs, will show the value and importance of purgatives in a still clearer point of view, and lead to a more discriminative employment of them.

A certain degree of arterial action being necessary to the healthy exercise of the secretory and excretory functions, it might be reasonably supposed that increase of such action would lead to a more energetic performance of these functions, and increased formation of what they respectively secrete, — a supposition which the evidence of facts amply confirms, one of the earliest effects occurring in a state of febrile excitement being an increased secretion of the natural mucus which lines the stomach and intestines. Of the existence of such superabundant mucus during inflammatory complaints, sufficient proof is afforded in the discharges brought off by appropriate evacuants, or occasionally by the natural efforts. With respect to the stomach, if the examination of its rejected contents be superficial, it may mislead, for the mucus, if of recent secretion, being clear and colourless, is not readily distinguished from the surrounding fluid. Its tenacity, however, furnishes a ready means of detecting and demonstrating it, for if a rod or wire of any kind be drawn through it and elevated, it will raise from the watery fluid, discharged by vomiting, the mucus diffused through it, and sufficiently display its dense and viscid nature. Similar secretions go forward at the same time through the whole intestinal canal, as evinced by the quantity of mucus which a dose of calomel, or of calomel and antimony, administered under these circumstances, expels. And to the power of these medicines in dislodging such secretions is owing much of the efficacy so long and so justly attributed to them in the cure of acute diseases. The increased secretions proceed immediately from the greater activity of the secerning vessels. These again derive their excitement from the greater abundance and more stimulant quality of the blood conveyed to them; and the effect of their increased action is to correct the stimulant property of the blood, by disposing of the nutritive constituents which render it unduly stimulant, and thus to allay indirectly their own inordinate actions. Hence the relief of the constitution by means of the improved quality of the blood may be fairly considered the final cause for which these secretions are increased, for which febrile excitement is generated. In this view we can perceive the importance of purgatives, not only as general evacuants, but also as specially promoting those curative efforts by which nature herself endeavours to throw off redundancies and minister to her own relief.

The want of sufficient attention being given to the peculiar effects produced by different purgatives may account for much of the uncertainty and indecision that have prevailed in the employment of them. This part of medical practice, indeed, has been much improved of late years; and the labours of several modern writers, of whom Dr. Hamilton and Mr. Abernethy are preeminently distinguished, have done much to assert for it the importance due to it. Still much remains to be investigated respecting it. If the mucous matter be recently formed, and in no great quantity, a common purgative will suffice to remove it, together with all such feculent lodgments as the bowels may contain. A source of injurious irritation is thus removed, the various secretory and excretory vessels are disencumbered of an oppressive load, and left free to perform their natural functions, or to renew their sanative efforts; and the process of nature instituted for the removal of redundancy and restoration of health goes uninterruptedly forward. If the mucous secretions be of older formation, consequently more viscid and tenacious and less easily expelled, the common purgatives fail to give relief, and a doubt is thus often cast on the propriety of employing purgative treatment. The patients may be misled, as many continually are, by false experience; but the practitioner should not fall into this error. The fault lies not in employing purgatives, but in not suiting those given to the effect required; for if a suitable preparation of mercury or antimony be in such case combined with the simple aperient, the result will rarely occasion

disappointment. If saline purgatives be given with the intention of cleansing the intestines at a time when they are coated with viscid secretions, the purpose will be very imperfectly answered, while if persevered in when general evacuation is no longer needed, and there is no febrile action to call for their use, they fruitlessly exhaust strength and do sensible injury. Even the powerful remedy which a combination of calomel, antimony, and drastic purgatives supplies, may be misapplied, and if rashly given when the bowels are irritable, with little mucus present, distress and injury may result, and an useful remedy thus fall into unmerited disrepute. In fine, by neglecting to ascertain the precise nature of the evacuation required, and to apply with accuracy the remedy suited to effect it, we must ever run considerable risk of disappointment in the effects expected from purgatives, and of so misapplying them as really to do injury in cases where purging, judiciously regulated, is the best if not the only means of cure. The quantity of mucus secreted in the stomach and intestines under febrile excitement, which implies a general increase of vascular action, is often considerable. It lines the whole canal, and when accumulated (and more especially when inspissated by long retention) is the cause of many powerful medicines passing through without producing their ordinary effects; for in consequence of the interposed mucus, the medicines come imperfectly or not at all in contact with the living fibre on which alone they can act. They pass, therefore, as if either the living fibre were torpid or the medicine inert, when neither supposition would be correct. This is signally the case with respect to the stomach, the accumulated mucus of which is often thrown off like a dense membrane. In this state of stomach we have oftentimes given tartarised antimony in grain doses quickly repeated to the extent of twelve or fourteen, ere vomiting could be excited, the matter discharged furnishing abundant evidence why such inordinate quantity was needed. We mention the circumstance here in order to enforce the expediency of judging on all occasions, not from the quantity of medicine administered, but from the effect produced; and, as the principle applies no less to the bowels than to the stomach, to impress the indispensable necessity of a constant inspection of the alvine discharges, without which it is impossible to form an accurate judgment either of the propriety of purging, the selection of purgatives specially indicated, the extent to which their operation should be carried, or the period for which their use should be continued.

It has been shown that the derangements of circulation incident to a state of plethora, whether absolute or relative, manifest an uniformity which serves to mark the nature of the morbid changes induced, and to illustrate the processes which nature institutes in her endeavours to effect her own relief. Redundancy of nutritive matter first excites the healthy functions to increased energy, tending to its appropriation by natural secretion: when too much urged this energy abates, and feebleness of arterial action ensues; to this succeeds a state of general excitement, such as is expressed by the term fever; and finally some local congestion or inflammation occurs, producing what is called a specific disease. From this view the dependency both of the general fever and local affection on the constitutional state is at once perceived; and the treatment by which these are severally relieved acquires thence a clearness and consistency which no speculative theory of disease has ever yet imparted. For absolute plethora in its simple state, it has been shown that depletion and abstinence, the remedies directly suggested by a knowledge of its cause, are those which experience proves to be most efficient, and which may alone give full relief. For the active fever and local inflammation induced by this condition, the same means are essential, and are still the most powerful of all that can be employed; though when these derivative maladies occur, other evacuations besides that of blood are needed, it being here required to call forth the energies of all the excretories of the system in aid of those constitutional efforts by which the febrile excitement is aroused. In relative plethora the morbid condition of the system is less simple, yet it still corresponds with the other throughout. Owing to the duration of morbid actions antecedently to the occurrence of febrile excitement, the constitutional derangements are more extensive; more functions are depraved; the difficulty of restoring these severally to a healthy state is increased; and a longer time is required to correct their aberrations and renovate their powers. During this period, too, various disturbances, originating in depravation of nervous function, become intermixed with the ordinary symptoms, complicating and obscuring the whole. To these latter we shall have occasion to advert more particularly by-and-by. In absolute plethora the purpose is simple. If the redundancy of nutriment be diminished, and a fresh supply withheld—in other words, if bloodletting and abstinence be carried to the requisite extent, the powers of nature, thus relieved, are amply sufficient to re-adjust all that is amiss, and perfect health becomes restored.

No artificial stimulus is here needed to arouse the natural powers; but, on the contrary, the chief care is to restrain them within salutary bounds. In relative plethora, while depletion and adaptation of diet are equally necessary as in positive, more care is necessary for maintaining in due activity the several secretories, and some degree of stimulant treatment requires to be combined, in order to excite and support those increased energies of the system by which alone this condition can ever be thoroughly rectified. Ordinary stimulants, however, which merely excite the heart and larger vessels, are inadequate to this end. Nay, they do mischief; for they lead to no effectual exercise of power, and from that which they do excite, exhaustion rather than benefit results. The great deficiency of power which here prevails is in the capillary vessels, and to depravation, abatement, or suspension of their functions, may all the coincident derangements of the frame be readily traced. The two most essential processes of animal life are nutrition and excretion. These are exclusively performed by the capillary vessels, on the due energy of which they are dependent. When from any debilitating cause these minute vessels fail in power, or become obstructed, both

nutrition and excretion must become impeded; and hence we can understand why emaciation often takes place, even when there is a redundancy of nutritive matter in the general circulation, available for nutrition if the capillaries could so dispose of it. It is hence also intelligible, how a debilitating impression made on the system has, through abatement or suspension of the capillary function, the direct effect of throwing back upon the mass of blood that which in ordinary course the capillaries would have disposed of, and of thus inducing a state of relative plethora. It is clear from this view, that the object of treatment in relative plethora is not merely to remove the relative excess, although this demands its full share of attention; but also to renew the activity of the capillaries, in order, first to re-establish their healthy functions as essential to the well-being of the general constitution; and secondly, by thus providing for the just appropriation of the nutritive matter supplied by the blood, to restore that balance between appropriation and supply without which health cannot subsist, and which the occurrence of plethora, however induced, never fails to disturb. We have stated that ordinary stimulants, which produce but transient excitement of the heart and larger vessels, are not the remedies here needed. What we require is an agency which, without exciting inordinately the general circulation, is capable of acting on the capillary vessels, and of arousing them to a renewal of their several functions both secretory and excretory. Such a remedy we happily possess in mercury, which is singularly endued with this peculiar property, and which, in consequence, affords a powerful agency in relieving the larger blood-vessels, when overcharged, from part of their excessive load, by causing it to be diffused more freely through their numerous and wide-spreading ramifications; and when the aggregate capacity of the minute vessels thus expanded and restored to the exercise of their natural functions, is estimated, there will be little difficulty in comprehending how mercury proves so powerful an auxiliary of bloodletting in relieving an overcharged state of the general circulation, as well as in correcting the congestions and other derangements to which this state gives rise. If the effects of mercury on the animal frame be examined, it will be seen that, however diversified, they all correspond in one respect—namely, in evincing increased action of capillary vessels. Mercury has the effect of increasing almost every secretion, and by capillary vessels all secretion is performed. It promotes transpiration by the skin, diuresis, and secretion of bile; it more especially excites the salivary glands; and there is reasonable ground of conjecture that it similarly affects the pancreas, to the increased secretions of which gland mercurial diarrhœa has been with some plausibility ascribed. It increases the intestinal discharges independently of its direct action on the bowels when taken internally, for mercurial frictions are well known occasionally to purge. In every effect which mercury induces this common character is observable, that capillary action is more or less excited. Now a renewal of capillary action is what has been shown to be needful for correcting the derangements incident to relative plethora, and hence the inestimable value of this remedy when judiciously administered, in restoring to health those who suffer under such derangements.

In absolute plethora the febrile action aroused suffices to impel blood into every extreme vessel, and thus to equalize circulation by extending it to every part where nature requires its full activity; and to effect this seems to be the great end for which febrile excitement is instituted by nature. In relative plethora this effort is more feeble, the natural powers being weaker, (indeed it is in this natural weakness that relative plethora has its origin;) and as every day but adds to the labour to be performed, while under the general depravation of habit the natural powers tend to further decline, we have little difficulty in comprehending why this state does not become aroused to those energetic efforts which are so often witnessed in the active fever of absolute plethora. To excite such effects then by the peculiar stimulus of mercury becomes an essential part of the treatment of relative plethora; and when in the correction of this state mercury is used with the necessary discrimination, and in aid of bloodletting, no course of medical treatment can be more successful, nor more strikingly illustrative of the principles by which it is guided, than that which this combination of depletory and stimulant agency supplies. The principle here adduced is confirmed by all that we know of the action of mercury, whether in its abuse or its use. Consistently with the views here presented, this action ought to be salutary only when the labour to be performed is not beyond what the animal powers are capable of sustaining. If the labour be too great, if inordinate plethora prevail, then must the excitement of mercury fail to effect its object, and the animal powers, exhausted by the vain effort, must still further decline. This operation of mercury corresponds exactly with the course of active fever where no bloodletting is employed. The powers exercised are in either case considerable, but the labour is disproportionate, and they sink under it. But if the labour be lightened by lowering the nutritive quality of the blood, (and this can only be effected with the necessary promptitude by bloodletting,) then will both febrile action and that of mercury accomplish all that is required from them.

We must here call attention to a physiological truth which requires to be borne in mind. When nutritive matter is introduced into the blood, if it find not an outlet by artificial bloodletting or natural hemorrhage, it must go through the processes of secretion and excretion ere it can be again expelled. If it be so redundant as to require these functions to be inordinately exercised in disposing of it, the respective organs lose power, and from the over-excitement sink even below the natural standard. Bloodletting, by lowering the quality of the blood, and lessening the proportion of its nutritive constituents, supersedes much of this inordinate and unnecessary labour, and thus actually saves animal power instead of expending it. In absolute plethora this is all that is required, for the natural powers thus relieved are fully equal to accomplish their own work. But in relative plethora the case is somewhat different. Here, while the nutritive matter

of the blood is relatively redundant, requiring to be reduced, the animal powers are also enfeebled, and the several functions dependent on the capillary vessels are all more or less depraved. In addition, then, to reducing the nutritive matter by abstracting some blood, it is here necessary also to excite both the general powers and the capillary actions, in a way more effectual than simple febrile excitement can accomplish. Here mercury comes appositely and powerfully in aid, and by its direct influence on the capillary vessels effects what the natural powers, even when aroused into febrile excitement, would under such circumstances be unable to perform.

An analogy has been traced between the action of mercury and febrile excitement; and if this be followed up by closer observation, the respective processes will appear little short of identical, the only difference being in the excitant by which these processes are instituted and maintained. In absolute plethora the redundant nutritive matter suffices to arouse the system to corrective efforts: in relative this is inadequate, and the excitement of mercury is needed for stimulating to due activity the arteries, more especially in their minuter ramifications. This it effects in a way so closely corresponding to febrile action, that when the full effect of mercury is produced, it would be difficult to show that its phenomena differ essentially in any respect from those of fever. There are induced a quick pulse, hot skin, white and furred tongue, muscular debility, increased secretions, attenuation,—in short all that characterizes simple fever. And further, if this state be neglected or maltreated, it passes into one which exhibits the whole train of typhoid symptoms—black and dry tongue, accumulation of sordes on the teeth, prostration of power, high nervous excitement, and finally death. These consequences are attributable, not to any necessary effect of the remedy, nor to any poisonous properties inherent, but to the constitution not being prepared by sensible depletion for its safe and salutary exhibition. When mercury is administered in unreduced plethora, and especially when its use is rashly urged, the effects are precisely such as result from febrile excitement, when, besides being inordinate in degree, it fails in its corrective agency. The excited powers, exhausted by their efforts, fall into a state of collapse, the object for which they were exercised is not attained, the capillary actions are either not renewed, or if renewed they are overworked, and thus again enfeebled; they are consequently incapable of ministering to the general restoration as they would do if their healthful functions were re-established; and the consequence is, that the constitution is left in a far worse state by the effort than if it were not made. Far different is the result when either febrile excitement or the action of mercury is regulated by the guidance which sound principles supply. If plethora be reduced, and a state of active secretion be maintained, then may either febrile action, or that of mercury, be rendered conducive to the restoration of health, through renovation of functions such as seen almost beyond the reach of other influences.

The evils occasioned by neglect of the principle here inculcated, are abundantly displayed in the history of syphilis; and we believe that all experienced surgeons are now agreed on the danger of administering mercury in an overcharged constitution.

Enough has now been stated to display the principles which should guide the employment of mercury in the treatment of relative plethora, and of the manifold diseases incident to this condition of the frame; and from long and extensive experience and close observation, both of diseases and the operation of remedies, we can confidently affirm, that if the principles here inculcated be applied to the elucidation of diseased conditions; if in these the attendant state of constitution be regarded rather than the specific disease, and at all events in connection with it; and if the treatment indicated by the foregoing principles be employed so as to correct the constitutional derangements, many an apparently formidable malady will insensibly subside without requiring any specific treatment to be directed towards it, its surest corrective being the removal of the causes in which it originated, and by which it was upheld.

The practical application of these principles in the treatment of relative plethora, is simple in the extreme. If the diseased condition be of recent occurrence, and the depravation of the capillary functions slight, very moderate evacuations and renewed activity of the secretory and excretory functions, with regulated diet, will suffice to restore health. But if the plethoric state have continued so long as to deprave materially the general habit; if the capillary functions have been so long inactive as to have become indisposed to a renewal of their healthy energies; if the secerning vessels have, through their abortive efforts, become obstructed and powerless; and if, through congestion or subacute inflammation, structural changes have commenced in any of the organs or tissues, then these simple means must fail, and some constitutional effort, such as is exerted under febrile excitement, is necessary for restoration. But as natural febrile action is in this case inadequate to effect what is required, we here need the artificial excitement which mercury supplies, to accomplish the purposes which medical treatment has in view. The indications by which the use of mercury is to be guided, are neither obscure nor equivocal. If there be the debility of incipient plethora, moderate evacuations will relieve the vital powers, and enable them to display their inherent energies. When febrile action is thus aroused, the course of procedure is clear, and if the powers called forth be adequate to effect perfect restoration, no artificial excitement can be needed. But should it be, as in the larger proportion of such instances will prove to be the case, that the natural powers are feeble and inadequate to maintain the curative processes by which a healthy state of capillaries is to be renewed; if the obstructions be considerable, and the indisposition of the capillaries to a renewal of their natural exertions be clearly marked, then is the stimulus of mercury indispensable, and for this end there exists not, in the wide range of medicinal agency, a remedy possessed of powers so certain or so manageable. We have medicines which emulate some of its properties; antimony promotes many of the capil-

lary secretions; iodine promises to afford much valuable aid of a corresponding kind; but so far as our present knowledge extends, we have no medicine entitled to rival mercury in the properties which the foregoing observations ascribe to it. When a soft, calm, and firm pulse evinces a healthful state of circulation; when the several secretories and excretories cease to display in their products a morbid condition; when under these changes the general feelings improve, and health progressively amends, it is quite needless to exceed the means by which a change so favourable has been effected, and far better is it to trust to this slow but sure process of amendment, and await the time necessary for completing it, than by over-anxiety for more rapid progress hazard the disappointment which too sedulous endeavours might occasion.

But when the constitutional efforts do not make perceptible advance in the removal of general indisposition and local derangement; when the pulse continues oppressed, the skin dry, the tongue irregularly coated or otherwise unhealthy, the excretions morbid, the aspect sallow, and the general feelings unrelieved, then if depletion have been employed, and carried to the extent which sound experience justifies, it becomes absolutely necessary to resort to that agency which mercury supplies, and to administer at intervals small and unirritating doses of this mineral, so as to excite the animal powers to the efforts necessary for relief.

It occasionally happens that in this use of mercury too much excitement follows, and from this circumstance its inexpediency has been at times somewhat hastily inferred. The occurrence may no doubt proceed from the medicine being unsuitable; but it may also take place either from plethora not having been sufficiently reduced, or from the medicine being too freely administered. In these latter instances, further depletion and reduction of dose are what reason would direct. Precipitately to withdraw the remedy under such circumstances, without trial of the expedients here proposed, would be little reconcilable with that knowledge of the operation of mercury which all should possess who venture to prescribe it. In general, it is advisable to continue its use until its constitutional effects are evidenced by slight affection of the gums; but this is not indispensable, for we have often seen its curative effects obtained without any soreness of mouth being induced. Much minute detail on what is called the alterative effects of mercury, and the modifications which its exhibition continually requires, might here be introduced, but it would encumber an article already too long, and it cannot be needed.

No morbid condition can more clearly illustrate the operation of mercury than that which the advanced stages of continued fever present. Such cases have often been consigned to us as hospital patients when the early treatment had proved unsuccessful. The phenomena of this stage of the disease we need hardly describe. Great emaciation, prostrate powers, a feeble and rapid pulse, black and dry tongue, lips and teeth covered with sordes, insensibility, with a train of corresponding symptoms, characterise this stage. Yet, appalling as is the condition here presented, we never despair of it, provided no organ essential to life have yet suffered irreparable injury. Stimulants to recruit power are of course needed; but the chief agent for exciting the several secretory and excretory vessels, and for renewing the activity of the capillaries generally, is mercury. By small doses of this, repeated at suitable intervals, the pulse is rendered fuller and firmer, the secretions improve, the tongue becomes moist and clean, sordes separates from the teeth and lips, consciousness returns, appetite revives, and sleep is restored. Large doses are not needed; from one to two grains of calomel, given three or four times in the twenty-four hours, will generally suffice. Aperients and nourishment are of course required, and wine to such extent as the existing debility may demand. This effect of mercury we have so often witnessed that we can entertain no doubt either of the correctness of what is here stated, or of the agency to which the amendment is owing. No subject in pathology can be more interesting than the progressive development of power and improvement of function which such a case presents. It has repeatedly occurred to us to see so much reaction thus aroused as to require actual depletion of blood at late periods of the disease to relieve the local determinations which resulted. In the same subject we have been obliged to apply leeches alternately both to the head and chest, in order to allay the respective local excitements. That these resulted from the use of mercury we were well assured, but, instead of withdrawing it under a false alarm, we relieved the local disturbances by depletion, continuing a guarded use of the mineral so long as its specific agency was required for the re-adjustment of the system.

The accordance of the principles maintained throughout this article with the best established doctrines of idiopathic fevers cannot fail to be perceived by those who have given to this latter any particular attention. Dr. J. Armstrong, in his excellent treatise on typhus, distinguishes three stages in the disease, namely, those of congestion, reaction, and collapse. It is in confirmation of his accuracy that a corresponding succession, differing only in the intenseness of each stage, may be traced in every instance where simple inflammatory action arises, a circumstance which claims for his theoretic views a high credibility, by showing that the essential phenomena of continued fever do not result from any peculiarity of character imparted by its special cause, but that they correspond accurately with the successive processes which nature institutes in the simplest febrile disturbances of the animal frame.

Even the minuter observations which we have made on the changes of the pulse, and which were derived from the examination not of idiopathic fever but of incipient plethora, correspond with what Dr. Armstrong states as occurring in the congestive stage of typhus, among the symptoms of which he notices "a quick, low, struggling pulse, *changeable as to frequency, and even irregular as to force.*" But the most impressive illustration of the debility connected with internal congestion, and of the effect of copious bloodletting in relieving it, is, perhaps, that which is furnished by the epidemic, or, as it is commonly termed, spasmodic cholera.

In the pamphlet published by the London General Board of Health, by authority of the Privy Council, the following passage occurs: "But the remedy which is described to have been most uniformly successful, when it could be used, is bleeding, and this even in cases where the pulse was scarcely perceptible at the wrist. This practice seemed to apply itself to the root of the disease, by relieving the congestion of the venous system, which was invariably found loaded on examination after death, and which congestion (though only an effect of the first impression made by the attack of the disease on the constitution) appeared to be the immediate cause of death. In the lighter cases, or in those of a severe nature which came under medical treatment before the pulse at the wrist was lost, or had become fluttering, bleeding was attended with the most decided advantage. The oppression of the chest, the burning heat of the præcordia, the spasms, the vomiting and purging, are stated in some instances to have ceased at once; at others, on a repetition of bleeding. In such as allowed a free abstraction of blood, these effects very uniformly occurred; but even in some, when the pulse was indistinct, bleeding was successful, if it could be carried to the extent of eighteen, twenty-four, or thirty ounces, the pulse rising in power and becoming more distinguishable in proportion to the flow of blood. If the pulse in this state of feebleness was distinct enough to give the finger the feeling of oppression, bleeding was almost always successful. The blood drawn was black, whether procured from a vein or an artery, and flowed with great difficulty, commonly first coming from the vein in drops, and gradually in a stream; but before it could be induced to flow with freedom the patient often required warm baths, frictions, external and internal stimuli, to produce a sufficient quantity for his relief. If a small quantity only could be procured, the heart seemed to feel the loss without being relieved, the bulk of the blood actually circulating being reduced, while the great mass of it, congested in the inferior and superior vena cava, did not make its way to the heart. The effect of bleeding was mechanical, and acted only as removing an obstruction to the passage of the blood from the distended venous system; and if not carried far enough to remove this impediment and allow the large veins to empty themselves into the heart, such weakness was produced as is occasioned by the loss of blood in a constitution worn out by disease." This statement of the Board of Health we adduce in preference even to the authorities from which it was derived. It was the result of deliberate and mature consideration of all the information which public records and private testimony could supply; it was issued to the public under a responsibility which must have precluded all slovenly examination of facts, all influence of speculative theories; and it hence carries authority as an announcement of facts, which no individual testimony could possess in an equal degree. It is difficult to conceive a correspondence more complete than that which subsists between the facts here recited and the pathological principles which we have endeavoured to illustrate throughout the present article.

It cannot fail to be perceived how intimately these principles are connected, not only with the morbid conditions described, but also with the whole course of medical practice. If such morbid conditions of the frame have any existence, they must more or less affect the progress and influence the treatment of a large proportion of diseases. Wherever they prevail it is obvious that the treatment of specific maladies cannot be wholly independent of them, and even where no plethora exists, the negative can only be ascertained by a familiar acquaintance with the phenomena which denote its presence. Nay, so many specific diseases depend wholly on the depravations of habit noticed in this article, that when the constitutional derangements are correct, the special diseases spontaneously cease. On every account, then, the doctrines of plethora, its rise, progress, and treatment, must be allowed to constitute an essential part of medical science.

But of all sciences, that of physic is perhaps the least simple. Its principles, individually considered, are clear deductions from well-established facts, and, so far, simple in their nature. But it very rarely happens that any one of them, however irrefragable, suffices for our guidance. Morbid actions, however simple in their origin, become so soon combined with others, whether derivative or contingent, that the assemblage manifested in every instance of advanced or specific disease loses all character of simplicity, and requires for its exposition a variety of knowledge, a clearness of conception, and an accuracy of judgment exceeding perhaps what any other earthly pursuit demands.

A most important complication of vascular derangements is that which is derived from coincident disturbance of nervous function; and so continually are these conditions intermixed, that the consideration of plethora would be incomplete if this source of complication were unnoticed. As a matter of fact, it is familiarly known that inflammatory diseases of the same general character and denomination present in different individuals different phenomena according to the degree of nervous irritability respectively attendant. The predominance of this latter may proceed from peculiarity of temperament, or from the influence of stimulants particularly exciting the nervous system, in operation antecedently to the special disease, and independent of it; or it may result from cerebral congestion or irritation incident to the febrile state which plethora is seen to induce. It is further known that nervous irritability, when in excess, is capable of producing derangements which so much resemble those of pure inflammation as frequently to mislead practitioners into employing active depletory treatment where this is unsuitable, if not absolutely injurious. It is time that these several conditions and their combinations should be more fully investigated and better understood, were it only for guarding against an error to which recent enquiries on this subject seem to tend,—namely, that of regarding the inflammatory and irritative states as opposite and contradictory; so that where one state is proved to exist, the other must, by implication, be considered as negatived. The truth of such a position we would not admit; and we are anxious to dis-

play the grounds of our persuasion in this respect, entertaining as we do considerable apprehension lest the views of nervous excitability which some able and discriminating writers have of late years presented, (or rather the practical evidences which they have adduced of this being preponderant in certain maladies which had been very generally regarded as purely inflammatory,) should withdraw attention from inflammatory action beyond what the writers alluded to contemplated or would have approved.

The morbid irritability which, simulating inflammatory excitement, gives rise to local disturbances liable to be confounded with pure phlegmasiæ, and which, however it may be temporarily alleviated by bloodletting, is eventually aggravated by it, while it is relievable by opium and ammonia, has been ably illustrated by the late Dr. Gooch in his valuable "Account of the Peritoneal Fevers of Lying-in Women," and also by Dr. Marshall Hall in an "Essay on some Effects of Intestinal Irritation," as in several other of his works. In all that these judicious and eminently practical writers have adduced respecting this condition, and the treatment required for its relief, we entirely concur; but in admitting fully the truth of their statements, we are anxious at the same time to impress that though the higher degrees of irritability may exist independently of plethora or of inflammation,—nay, may have their origin in actual inanition or in excessive loss of blood, the same nervous depravation is continually found combined in every proportion with plethora, inflammation, and congestion; and that when it is so combined, the treatment, to be safe and effectual, must have relation to both sources of disease. In proportion as plethora and inflammatory action prevail, must depletory treatment take the lead; and according as irritability is excessive, will opium and stimulants be needed. To discriminate these respective conditions, then, so as to assign to each its appropriate treatment, is the point to which practical observation would be most beneficially directed. And in this scrutiny much advantage will result from founding diagnosis not on one or two prominent symptoms, but on the whole assemblage; among which, as was remarked in a former part of this essay, such harmony should subsist that no individual symptom should be contradictory of what the others proclaim. When such contradictions present, then, instead of leaning exclusively to that side to which the balance inclines, each class of symptoms should receive its appropriate consideration, and be referred to the principles in which it originates. In the morbid conditions under discussion, it is not difficult to distinguish the purely inflammatory cases from those in which excess of irritability is combined. In the latter, while the disproportionate degree of irritability should itself excite suspicion, a scrutiny of symptoms will show that these do not all in equal degree denote such activity of inflammation as the prevailing irritability would imply. The pulse, temperature, and tongue do not present that correspondence of derangement which is usually attendant on purely inflammatory action. The pulse, however accelerated, (and in such cases it is often inordinately so,) wants the firmness which belongs to inflammation. The temperature is not always in accordance with the high sensibility evinced by particular parts of the frame; and the tongue, instead of being dry or furred, is oftentimes moist and preternaturally red. So endless, however, are the varieties induced by the combinations which occur, that it would be impossible to render a distinct account of them by any description, or to do more than to point out the sources of disease to which the practitioner's own observation should be directed.

For plethora and inflammation the appropriate remedies, as we have often stated, are bleeding, purging, and antiphlogistic treatment; while morbid irritability yields but to opium and other sedatives, combined, as occasion requires, with cordials and tonics. In proportion as either condition prevails, must its appropriate remedies be combined in the treatment; and on the accuracy with which these remedies are severally adapted does much of the success of medical practice depend.

The subject is much too copious to be discussed fully in this place, where our chief object for introducing it is to impress a warning against hastily inferring, that because irritability predominates, inflammation or congestion is not co-existent. Even where morbid irritability results from exhaustion or inanition, congestions continually occur which call for topical bleeding, however unsuited depletion may be to the constitutional state existing, and even though to sustain strength by tonics and nutritive diet may be at the same time required. This is well exemplified in a state of disease of frequent occurrence, and with which most practitioners must be familiar.

Females under too protracted lactation fall into ill health, marked by exhaustion, and attended with various nervous derangements. This state is common among the poor, who, for various reasons, are accustomed to suckle their children for long periods,—even for two or three years. Pallid aspect, disordered digestion, irregular bowels, and acute pains of head, with prostration of strength and great nervous irritability, are the prominent features; but the whole condition thus induced is so peculiar and characteristic that they who are familiar with it are at once led to a knowledge of the cause by inquiries which they might otherwise not think of making. Taught by experience, we have oftentimes, among the out-patients of the hospital, discovered the fact by direct inquiry where there was nothing save the general character of the disease to induce suspicion of the woman being engaged in suckling; there being either no child produced, or one able to walk by its mother's side. Weaning the child is here the indispensable requisite; and its effects are quickly displayed. They are assisted by mild aperients combined with sedatives, cordial remedies, and sustenance. No state would appear on principle less suited for evacuant treatment than this; and under this impression we were for a long time averse to relieving the head by any direct depletion. The inveteracy of the headach, however, forced us to the application of leeches; and the prompt relief which they afforded soon removed all scruples on this score. A few suffice; six or eight applied to the temples give in general all

tne relief required; but nothing can be more decisive, or more strongly marked than the benefit which they thus afford.

We do not say that all such cases require leeching, but the attendant headach yields readily to this remedy when all others fail to subdue it. The only inference which we can draw is, that notwithstanding the general debility and perhaps by reason of it, the vessels of the brain become congested and unable to unload themselves; that the topical bleeding, by lessening their contents, enables them to contract and recover their natural diameter, and with it the power of carrying on the circulation so tranquilly as no longer to disturb the cerebral functions.

The above state only displays congestion as coinciding with irritability and exhaustion; but the instances are of daily occurrence in which morbid irritability is complicated in every variety with relative plethora; and when these states are so combined, it is quite as necessary to correct the plethora as to allay the irritation, the most effectual way of restoring health in such case being, not to pursue any exclusive system, but, guided by experience, to give to each derangement the consideration which it specially claims, and to combine the respective remedies as the prominent derangements may severally demand. A knowledge of the principles on which each class of remedies should be employed furnishes the best guidance for regulating those combinations which such complex states of disease must ever require. One of those conditions, at least, we have endeavoured to illustrate in the foregoing pages; and however we may have failed to do justice to the subject, it is hoped that sufficient ground has been shown for pursuing the inquiry, and a motive furnished for other observers to complete what we must necessarily leave imperfect.

Before concluding this article, it is necessary to offer a few remarks on the vitiation of blood which arises from redundancy of excrementitious matter, regarding this in its simple state, unconnected with the various degrees of plethora with which it is so continually combined. In doing so the motive is not so much to designate the morbid condition as likely on its own account to become an express object of medical discipline, as to establish the principles which should govern its treatment, when, as continually happens, it is found combined with other derangements. The general phenomena which denote this condition are, a sallow aspect and dusky skin; the pulse low, soft, and compressible; the surface of the body for the most part harsh, dry, and obviously deficient in natural transpiration; the tongue moist, clear, red; the appetite capricious, often craving and voracious, with an endless train of dyspeptic ailments; the alvine discharges inveterately foul, dark, slimy, pitch-like, and exhibiting no trace of healthy fæces; the urine high-coloured, depositing more or less of dark, often fetid sediment: these, with decline of flesh and strength, are the general characteristics of this state. The condition itself we believe to arise from the accumulation in the blood of excrementitious matter imperfectly discharged, and the depraved state of the several secretions we regard as resulting from the laboured though ineffectual efforts of the constitution to accomplish, through their agency, its own purification. It may give a clearer conception of this condition to contrast its phenomena with those which characterize nutritive plethora. In the latter the general aspect is more full and florid; the surface is hot and dry, or inclining to moisture; the pulse hard and frequent, or full, strong, and bounding; the tongue white and furred; the stomach inclining to nausea, with thirst; the stools feculent, though foul, and charged with mucus.

In specifying the symptoms of excrementitious accumulations, it may be imagined that we have included several which belong to the different forms of hepatic disease. That they are frequently regarded as evidences of diseased liver, and treated accordingly, we are well aware; but that they are certainly to be met with where there is no organic lesion of this viscera, nor any particular functional disturbance of it, we are fully convinced. It is true that the functions of the liver are, in common with those of the whole alimentary canal, greatly depraved, but they are so not from any primary defect or derangement of their own powers, but from being required to act inordinately on a vitiated mass which nature is sedulous to purify.

According as nutritive plethora becomes more or less combined with this state, the constitutional efforts increase, and various degrees of febrile and inflammatory excitement ensue. In proportion as this excitement is energetic, and as measures of suitable activity are employed for its relief, the vitiated state of the blood becomes corrected, the secretions and excretions improve, and the general health and strength amend. The increased secretions from the bowels seem to be the discharge by which nature aims at getting rid of such impurities. To promote them, therefore, by suitable purgatives, at the same time supporting the strength by moderately nutritive diet, is the first indication.

When relief, to a certain extent, is thus afforded, the powers of the constitution rally, and a febrile effort is made to assist in the work of purification. According as this advances, depletion should be more active and the diet less stimulating. When sufficient excitement exists to warrant the employment of bloodletting, we may then consider the curative process as in the most favourable train. Perhaps the powers of the constitution are hardly adequate to rectify any high degree of this derangement without the extraordinary effects which a state of febrile excitement supplies, and hence we see experienced practitioners often hail the appearance of febrile symptoms in chronic maladies as announcing a more remediable form of disease.

In every view that can be taken of this condition, it must be considered as intimately connected with the state of cuticular excretion, from defect of which it is more likely to arise than from any other cause. When we reflect on the large amount discharged by this excretory under a healthy state of the system, and that, according to accurate experiments, more than one-half the ingesta is carried off by transpiration, it will be readily conceived that great excrementitious accumulation must result from impeded cuticular excretion. This matter being in consequence thrown

in inordinate quantity on the other excretories, it can excite little surprise that their ordinary functions should be thence disturbed, or that their several secretions should present a morbid character.

A constitution naturally feeble, especially if exercise be inadequately taken, sends the blood to the surface too languidly for the exhalant arteries to act with full power, whence excrementitious accumulation commences; the effect of this being directly debilitating, it serves to aggravate the cause, and thus the foundation is laid for a broken constitution and many inveterate chronic diseases. The best preventive of this diseased condition is, unquestionably, exercise, and in slighter degrees of it this would also be the most effectual cure; but when great depravation of habit has already taken place, there is neither the capability of taking adequate exercise, nor would it alone, under such circumstances, succeed. To be effectual it should be carried to the extent of producing some moisture on the skin, as the only sure evidence of the blood being impelled with sufficient force into the capillary vessels. The various forms of warm bathing are of great value, especially those which combine frictions and other means of softening and detaching hardened cuticle. That of the Russian vapour-bath, noticed by northern travellers, and so accurately described by the late Dr. Clarke, would appear eminently calculated for establishing a healthy state of skin, and an adequate activity of cuticular excretion.

E. Barlow.

PLEURISY, PLEURITIS. *Gr.* πλευρῖτις, from πλευρὰ, *the side*, also the membrane that lines the ribs, *the pleura*. Pleurisy signifies inflammation of the serous membrane which lines the cavity of the chest and invests the organs of respiration therein contained. Modern pathology has narrowed the application of this term, which, in the earlier ages of medicine, was employed to express pain of the side, no matter what tissue was the seat of the uneasy sensation, provided it was acute in its character and accompanied with fever. The frequency of the complication of pleurisy and pneumonia led many to suppose that the former was so essentially connected with the latter as to be incapable of an independent existence. It is, however, now clearly established that, although the parenchyma of the lung, and its enveloping membrane are often involved in the same inflammation, still there is no necessary connection between the affection of the one and that of the other.

If adhesions between opposite surfaces of serous membranes are to be looked upon as evidence of pre-existing inflammation, the frequency with which we meet with this morbid phenomenon between the pleural surfaces warrants us in asserting that no organ or tissue in the body is more subject to inflammation than the pleura.

Pleurisy presents itself under so many varied forms, that we shall find it difficult to exhibit it in one general description. It may be acute or chronic; it may affect one side of the chest or both sides; it may be general, involving the whole of one side, or partial, only involving part of one side; it may be simple or complicated; the complication may be either accidental or essential, and in the latter case the pleurisy and its complication stand to each other in the relation of effect and cause.

I. Acute Pleurisy.—The anatomical characters which the pleura affected with acute inflammation presents, consist of change of texture and change of secretion. We have also to consider the changes which the lung, compressed by the effused fluid, undergoes both in form, volume, situation, and other relations.

The inflamed pleura exhibits numberless minute capillary vessels carrying red blood; these vessels anastomose freely among themselves, and present injected patches of various forms. Sometimes the injection is so general as to appear like an ecchymosis. Careful anatomical examination proves these injected vessels to be situated in the subserous cellular tissue; and that what was considered an actual thickening of the serous membrane in the first stage of inflammation, is due to a serous infiltration into this cellular tissue, as well as to a loosening of the connection between the serous membrane and the subjacent tissue by the increased calibre of the capillaries, now carrying red blood. In some cases we can peel off the serous membrane, and thus prove the pretended thickening to be nothing more than what we have just stated.

Inflammation of the pleura induces changes both in the quantity and in the character of the ordinary serous exhalation. The first effect of inflammation upon the exhalation of a serous surface is, if not completely to suppress it, at least to diminish it very considerably; so that the dry surfaces have no longer that easy gliding motion which it is the physiological object of this lubrefying fluid to maintain. After an interval varying from an hour to two or three days from the commencement of inflammation, the serous exhalation is much increased in quantity, or, to adopt the language of pathology, the inflammation terminates in effusion. Laennec objects to this mode of expression, as calculated to convey an erroneous idea as to the time when the effusion begins to take place, as he is of opinion that in serous membranes the inflammation and effusion commence at the same moment, and proceed *pari passu*. With this, we must confess, our experience does not agree; and although in the larger cavities, viz. the abdomen, heart, and chest, our examination may not be capable of that degree of precision which would enable us to pronounce with certainty upon the point, still there are other cavities in which the train of morbid phenomena takes place more immediately under the cognizance of our senses, and where we have an opportunity of recognising a determinate interval between the supervention of the inflammation and the effusion; for instance, the joints and the tunica vaginalis testis. In iritis, we have ocular demonstration that it is some time after the pain has announced the inflammation, that the increased secretion of the aqueous humour takes place, causing an unusual prominency of the cornea.

The fluid effused into the cavity of the chest, in acute pleurisy, varies considerably in quantity; sometimes not exceeding an ounce, at other times amounting to several pints. When it is consider-

able, and has exercised a pressure upon the yielding parenchyma of the lung, reduced it to its smallest possible dimensions, and pushed down the diaphragm so as to cause the viscera placed below it to be felt lower than their normal situation, viz., the liver on the right side, and the spleen upon the left, it seems to be next directed against the walls of the chest, and produces a change in the form of the side, to which we shall have occasion to advert when we come to enumerate the physical signs of acute pleurisy.

The effused fluid presents itself under very various appearances. It may be colourless, transparent serum; or we may find flocculi of lymph floating in the serum without affecting its transparency; or, again, some of the lymph may be, as it were, dissolved in the serum, and, rendering it turbid, may impart to it an appearance resembling unclarified whey. Again, it may be a greenish fluid made up of serum and pus in various proportions, and approaching to each of these fluids in colour and consistence, according to the proportions in which they enter into its composition. Or it may be unmixed pus, resembling in its sensible qualities the matter of a phlegmonous abscess; and in this case the disease is ushered in with a strong rigor, the ordinary announcement of suppuration. Lastly, it may be either pure blood, or the ordinary serous effusion more or less deeply tinged with this fluid; the blood in this instance may be forced out either from the capillary vessels of the pleura in a high state of orgasm, or from the vessels developed in the organized false membrane.

In a case of acute pleurisy, which we have had recently under our care, and in which the urgency of the symptoms required the immediate performance of the operation of *paracentesis thoracis*, the fluid drawn off was of a yellowish colour and oily consistence, very much resembling in appearance copal varnish. On remaining a short time in the vessel in which it was drawn, it was converted into a tremulous jelly, and after some hours resolved itself into two distinct parts, a thickish crassamentum floating in a thin serum; it in fact very much resembled the blood without its colouring matter. The fluid having collected again, it became necessary, in the course of a fortnight, to repeat the operation, when we found the effusion to present very different sensible properties from those of the original fluid; it was of a greenish colour, and though apparently of a homogeneous consistence, on standing a short time, it separated into a thick, purulent sediment and a thin, greenish, supernatant fluid. This operation afforded a very temporary relief: the individual died in four days, and on examination we found not less than eight pints of thick purulent matter (such as is met with in a phlegmonous abscess) in the left side, and both pleura pulmonalis and costalis densely coated with lymph. The difference presented by the effusion on three different occasions constitutes the interesting feature of this case. Andral, in the second volume of his *Clinique Médicale* (*Sur les Maladies du Poitrine*,) mentions a case in which the fluid effused into the pleura resembled the jelly of meat.

A portion of the fluid effused in pleurisy has a natural tendency to pass to the solid state; from thence we have the false membranes, which present so much variety in their organization, form, extent, consistence, and thickness. The coagulable lymph is scarcely deposited upon the free surface of the pleura when it becomes solid. In the first instance it is a soft, whitish mass, exhibiting no appearance of organization or vitality; but soon red points make their appearance in it, which, elongating themselves into red lines, present unequivocal characters of vascular canals, and, passing beyond the lymph,—the matrix of their development,—proceed to inosculate with the vessels of the pleura, and thus establish a communication between the circulation of the false membrane and the general circulation. It is impossible to fix the time when organization takes place in these false membranes; nor is it easy to determine to what special influences this process is subject, evidences of such organization being found in false membranes, the result of pleurisy of a few days' standing, and being wanting in others of as many months' duration; thus, at least, proving that time is not the sole regulating circumstance.

The form assumed by the lymph deposited on the pleura is very various; sometimes it is deposited in isolated drops, having either the appearance of transparent vesicles or of miliary granules; at other times they closely resemble tubercles. In the differences presented by the lymph deposited in this form, we recognise the grounds of the opinion that hydatids are the form under which tubercles first present themselves, the transparency of these globular concretions countenancing such a belief. In a case of cancer of the lung, in which the cancerous matter presented itself in all the intermediate stages of development between hardened scirrhous structure and soft, dissolved, encephaloid matter, we found lymph deposited in the form of these isolated drops upon the pleura of the opposite lung, while the lung itself was quite free from disease. We suspect that lymph is the rudiment, or matrix, of all these morbid growths, which derive their special character from the peculiar cachexy of the individual.

Sometimes the lymph covers a greater or less extent of the pleura, in the form of concretions of variable density. The surface of these concretions is sometimes smooth and polished, sometimes it is rough and unequal, and sometimes it has an areolated, honey-comb appearance. In many cases, these concretions are converted into cellular bands, of variable length, connecting the two pleuræ, and are often found traversing the effused fluid. These bands acquire all the characters, both anatomical and pathological, of cellular tissue; they are subject to dropsical infiltration, and in jaundice present a yellow hue; they are often the matrix of morbid developments. That these bands do not fetter the motion, or in any way interfere with the function of the lung, is abundantly demonstrated by the fact of the frequency with which we meet them, in our necroscopic examinations, where we had no reason to suspect them during life.

The false membrane varies in thickness in different instances; sometimes it can be removed from the subjacent pleura in the form of a thin pellicle, not exceeding the thickness of the pleura itself. Most commonly the thickness of the false

membrane greatly exceeds the natural thickness of the pleura, and it seems to be made up of several distinct laminæ superposed. We have seen this membrane an inch thick, and the laminæ of which it was composed admitted of separation like the different laminæ composing the coagulum of an aneurismal sac.

As the false membrane resembles cellular tissue in its properties, it is subject to all the transformations of structure of which this latter texture is susceptible; thus it may be converted into cartilage, fibro-cartilage, or even into bone. It is this membrane, converted either into cartilage or fibro-cartilage, which, in phthisis pulmonalis, establishes such an intimate union between the pleuræ pulmonalis and costalis as to defy our utmost efforts to separate them.

The false membrane may be the matrix of different accidental developments, of which tubercle is by much the most frequent. We often find the surface of the membrane studded with small miliary tubercles: at other times we find these bodies in the substance of the membrane in their different stages of softening. We have no precise data whereupon to average the time when tubercles begin to form in the false membrane; and though we believe they may develop themselves within a very short period, we conceive the work of tuberculization in general to be a slow, insidious process, even in organs most essential to life.

The lung of the side, when the effusion exists, deserves our attention, both in reference to the position which it occupies, and the changes which it undergoes in its proper structure. In general the effused fluid tends to press the lung into the space beside the vertebral column, and when it is in considerable quantity, the organ is reduced to a thin lamina, so that sometimes it is not easy to find it, and thence we have heard of its having entirely disappeared. Adhesions will of course modify the position of the lung, and protect a portion of it from pressure. Sometimes the lung is applied against the ribs by being pressed backwards and outwards; at other times it is completely suspended in the fluid. In general the only change induced in the lung, pressed upon by the effused fluid, is a diminution of size, the mechanical effect of the peculiar circumstances in which it is placed. The air is squeezed out of it. The organ becomes more dense and less crepitating than natural; it assumes very much the anatomical characters of a fœtal lung; it has a smooth, uniform appearance, and does not tear as a portion of hepatized lung will do; its vesicular structure has quite disappeared, and even the blood-vessels are flattened and exanguious: the bronchial tubes become contracted in their calibre. Its resemblance to a portion of muscular tissue which has been submitted to maceration has procured for it the expressive term of carnification.

Tubercles may form in the compressed lung, and there undergoing their ordinary changes, will modify the symptoms of the disease; still it more frequently happens that the tubercles already existing in the lung, in softening, perforate the pleura, and give rise to that modification of pleurisy which might with propriety be termed *pneumothorax*. (Πύον, pus, πνεῦμα, air, θώραξ, chest.)

General Symptoms of Acute Pleurisy.—Acute pleurisy is well entitled to a place among the Pyrexiæ, from the symptoms of high febrile excitement with which it is in general announced; to these symptoms are superadded pain in the side, difficulty of breathing, a hard dry cough, and, usually, decubitus upon the unaffected side: upon these follow, sooner or later, a dulness of sound or absence of the ordinary resonance of the affected side when percussed, a peculiar modification of the voice designated ægophony, and bronchial respiration; then the complete absence of the respiratory murmur, and a palpable dilatation of the affected side.

The febrile symptoms of acute pleurisy are not marked by a uniform intensity. When the disease prevails as an epidemic, these symptoms partake more of a low typhoid type, and considerable derangement of the digestive apparatus holds a prominent place amongst them. The pain is unequivocally the most constant symptom of acute pleurisy; it is the one which especially attracts the patient's attention, and which, from the expression of anxiety and suffering which it imparts to the countenance, is seldom overlooked by the physician: it is described as a sharp, lancinating pain, increased by coughing, by inspiration, by pressure in the intercostal spaces, or by lying on the affected side; its situation is generally referred to near the mamma, and is felt in a very circumscribed space, no matter what may be the extent of the inflammation. It is not easy to explain why this should be the usual situation of the pain. Morgagni attempted to account for it by the greater mobility which this point of the chest presents, as being equally distant from the apex and base of the thorax, and from the sternum and spine. Though the point mentioned be the most usual seat of the pain, still it may be felt in any part of the side, or even in the opposite side, without this side participating in the inflammation.

When pleurisy depends upon tubercles in the pulmonary tissue, the pain is felt in parts of the chest corresponding to the situations of the formation of these foreign bodies; hence in the early or nascent stage of phthisis pulmonalis, we hear the frequent complaint of pain under and above the clavicle, in the hollow of the axilla, or between the shoulders, this pain indicating the existence of tubercles in the apex of the lung, the usual seat of their earliest development. This symptom of early phthisis is of much practical value, as it assists our diagnosis at a stage of the disease when the stethoscopic signs are equivocal, and when treatment interferes with most prospect of success.

When the pain is confined to the margin of the ribs, it is not always easy to determine whether it depend upon inflammation of the thoracic or of the abdominal serous membrane, and the difficulty is increased by the fact that jaundice has followed upon unequivocal pleurisy by an extension of inflammation of the pleura lining the diaphragm. Morgagni mentions a case in which Valsalva mistook the complication of jaundice for the primary disease, and overlooked the less palpable signs of a pre-existing pleurisy, proving how difficult it is

to establish a certain diagnosis when the situation of the disease is a point where many organs are, as it were, placed in the same parallel of latitude, and when the disease itself is not marked by any striking functional derangement. The pain is seldom constant, but is brought on by every thing calculated to impress the slightest motion upon the affected side; it sometimes assumes an intermittent character, and returns with a regular periodicity.

In the first moments of acute pleurisy, the respiration is marked by a peculiar nervous hurry. Nature is instinctively aware of the pain produced by a full inspiration, and therefore avoids it; she compensates for the smallness of the volume of air admitted at each inspiration by the frequent repetition of the act, and hence the respiration is short, hurried, and jerky (*saccadée*). When effusion has taken place, the dyspnœa depends upon a different cause, viz. the mechanical obstruction to the expansion of the lung, and is in proportion to the extent of the effusion and suddenness with which it has taken place. This latter circumstance has much more effect in embarrassing the respiration than the former, as we have known cases where individuals were quite unconscious of any thing affecting their chest, while at the same time there existed unequivocal evidence of extensive pleuritic effusion; and this arose from the organs having had time to accommodate themselves to the encroachment upon their functions. Should the opposite lung be affected either with bronchitis or emphysema, the dyspnœa will be more distressing.

The characteristic cough of acute pleurisy is a short cough, either dry, or accompanied with a thin mucous expectoration: should the sputa be more abundant or deviate from this character, we may suspect a complication either of pneumonia or bronchitis. The cough is often wanting altogether, or is so slight as to attract the attention of neither the patient nor the physician.

The difference of opinion which obtains among systematic writers upon the subject of the *decubitus*, or position of the patient in pleurisy, proves at least that it is not constant, and therefore cannot be exclusively relied upon as a diagnostic sign; still we may say that, as long as the acute lancinating pain of the side continues, the aggravation of it, caused by the pressure when lying upon this side, makes the individual seek the more easy position, either upon the opposite side or upon the back. When the pain has ceased, and extensive effusion taken place, the position, before avoided, is now adopted; because the effusion, interrupting the function of one lung, and placing it, as it were, *hors de combat*, a necessity for greatly augmented action devolves upon the other; and in order to favour this, nature instinctively points to the position which allows the easiest and most unembarrassed play to those muscles whose province it is to dilate the unaffected side of the chest, and this position is upon the affected side. It is only when the effusion has been sudden and considerable, when the respiration has (if we may be allowed the expression) been taken by surprise, that nature seeks to relieve herself by particular posture. It may happen that a fresh attack of inflammation in the side originally affected, or the lung hitherto free becoming involved, will produce the necessity for a certain position, to which nature in the first instance seemed to be indifferent.

Physical Signs. — In the earliest stage of acute pleurisy, there is no physical sign to mark its existence.

[Early in the disease, a rubbing, creaking, or friction sound is heard, which may indicate that the secretion from the pleura has been arrested by the inflammation, or, what is more general, it indicates that plastic lymph has been thrown out, the consequence of which is the friction — *frottement* — which, however, may be so slight as scarcely to merit the name of *frolement*, or "slight grazing sound;" but at other times is so loud as to resemble the "leather creak" — *bruit de cuir neuf* of the French. These signs, when combined with the general symptoms, are valuable in the diagnosis; but they are not of long duration, and may not, therefore, be heard. Friction sounds occur, also, in interlobular emphysema, and as this pathological condition does not speedily change, they persist longer. Recent researches, as remarked by Dr. Williams, (*Lectures, &c., on the Chest*, Amer. edit. p. 153, Philad. 1839,) would seem to show, that, as in the case of peritonitis, the sounds are not often produced in pleurisy, unless the lung is at the same time pressed against the chest by a tumour, or by effusion, or is partially distended by emphysema or tuberculous or other deposits. The sounds are generally most audible in the central parts of the chest, owing to the motion of the pleuræ upon each other being most marked in that situation; and in order to be heard, the patient should lie on his abdomen.]

When effusion takes place into the cavity of the chest, its extent is marked by percussion of the side yielding a dull dead sound, instead of its ordinary clear tympanitic resonance. This dull sound, it is true, may arise from other causes than from fluid effused into the cavity of the pleura; it may be owing to solidification of the pulmonary tissue, the effect of pneumonia; or to some morbid growth formed in the lung; still we can take such advantage of this sign as will enable us to determine upon what it depends; for although Laennec denies that fluid effused into the cavity of the chest can change its place, and states that it arranges itself between the lung and the walls of the chest, the experiments and examinations of Piorry on this subject, concurring with our own experience both during life, and confirmed by examination after death, enable us to assert that this fluid, being specifically heavier than the lung in its natural state, will displace it, and gravitate towards the most dependent part, and thus by change of position of our patient shall we be enabled to change the results both of percussion and auscultation. We believe the only internal limitation to the displacement of the lung to be the root of the organ; and when the effusion is considerable, and we examine the patient in the sitting posture, the weakness, if not the complete absence of respiration and dulness of sound, are owing to the fluid having pushed up, and now occupied the place of the lung; but as the root of the organ is its fixed point, when the fluid rises above its level, it is now that it presses upon it on

all sides, and when it has filled the cavity, the lung is, as it were, suspended in it, and, being retained here, undergoes different degrees of compression according to the extent of the effusion. The analogy of the fluid in ascites, displacing the intestines, confirms the view that we have just taken of the displacement of the lung by the pleuritic effusion. Adhesions between the pleura pulmonalis and costalis will prevent the fluid displacing the lung; and if we did not keep this fact constantly in view in our examinations, we should often be misled. We well remember the embarrassment which the usual phenomenon of distinct bronchial respiration produced in a case of unequivocal pleuritic effusion, related by Dr. Graves in the fifth volume of the Dublin Hospital Reports, and which an adhesion between the pleuræ pulmonalis and costalis afterwards accounted for. It is only when the dulness of sound and absence of respiration present themselves when we see the patient for the first time, that we can ever be at a loss to determine whether they depend upon pleuritic effusion or solidification of the lung; for the short time in which the whole side, or even its inferior half, will yield a dull sound, (sometimes occurring within a few hours,) is conclusive of its being due to effusion and not to hepatization, which is a very gradual result, and is always preceded by the crepitating râle. We may state generally that the sudden, equal, and uniform absence of respiration and dulness of sound are peculiar to pleuritic effusion.

When the effusion is very abundant from the first moments of its formation, the respiratory murmur ceases to be heard in any part of the chest, except along the vertebral column, where it is still perceptible for the space of about three fingers' breadth, although more feeble than on the opposite side. When, on the contrary, the effusion is gradual, the respiratory murmur begins by being a degree fainter, and continues to diminish its intensity until it is entirely lost. The respiratory murmur will survive the dulness of sound sometimes for days. When it has ceased in all other parts except beside the spine, it will often continue to be heard under the clavicle, in consequence of the frequent adhesions between the pleuræ pulmonalis and costalis in this situation in phthisis. To the cessation of the respiratory murmur or vesicular respiration succeeds a peculiar modification of respiration, which, from its apparent dependence on the air not penetrating beyond the larger bronchial tubes, has been termed *bronchial respiration*. As this same character of respiration exists in solidification of the lung in pneumonia, we may presume that it depends upon the same cause in both cases,—namely, the peculiar condition to which the pulmonary parenchyma has been reduced, in one by the compression of the fluid, and in the other by a deposition of foreign matter into its proper structure; so that the phenomenon would seem to depend upon the air entering the bronchial tubes, placed not in the midst of their ordinary spongy medium, but of a dense solid structure, and therefore better calculated to convey every modification of sound, whether of voice or of the entrance of air; furnishing us in the former instance with *bronchophony*, and in the latter with *bronchial respiration*.

The voice, as heard by the stethoscope, is observed to acquire a particular character in pleuritic effusion, which led Laennec to regard it as one of its most characteristic signs. From its resemblance to the shrill, jerky, tremulous sound of the goat, he has termed it *ægophony*. (See Auscultation.) This phenomenon is most perceptible about the inferior angle of the scapula, and in the space comprised between the posterior margin of this bone and the spine, and is found to exist only when the effusion has attained to a certain extent, and to cease when it either goes beyond or falls short of this: hence it is not met with either in the very early or advanced stage of pleurisy; and when it has been present and disappeared, its return is hailed as indicative of progressive absorption of the effused fluid. Laennec ascribes it to the transmission of the voice through the compressed lung and the fluid interposed between the lung and the side of the chest. As we before stated that our own experience, confirmed by Piorry's experiments, made us question Laennec's opinion of the stratum of fluid interposed between the lung and side of the chest, of course we cannot admit his *rationale* of the phenomenon, as far as relates to the transmission of the voice through this hypothetical interposed fluid. As the most experienced stethoscopists allow that they can with difficulty distinguish between ægophony and bronchophony, we believe the former to be a mere modification of the latter, and to differ only in the structure of the lung not having undergone an equal degree of compression: hence we see the reason why, in the earliest stage of pleuritic effusion, the compression has not been sufficient to produce the phenomenon; as the effusion increases, the compression is greater, and the phenomenon appears, the effusion increases still more, and ægophony gives place to bronchophony; as absorption takes place, the compression becomes less, and ægophony appears again; hence we have equal reason to hail the return of this phenomenon as an indirect expression of the diminution of the fluid, but an immediate result of the diminished compression of the lung, and not of the diminished interposed fluid through which the voice is transmitted.

When the effusion is considerable and has formed within a short space of time, the respiration in the opposite lung becomes puerile. The increased action which has devolved upon this lung strongly predisposes it to disease, differing, however, from the original affection: that is to say, the lung is more likely to become consecutively affected either with bronchitis or pneumonia than with pleurisy. When pleurisy is double, the two sides have become simultaneously affected, and their respective affections proceed *pari passu*.

When the effusion has proceeded to a considerable extent, it produces a change in the side, consisting in an actual increase of its size and form. It is remarkable how small a difference between the two sides, as ascertained by actual measurement, will strike the eye; an increase of six lines will have this effect. The change of form of the side consists in its becoming more rounded, and in the intercostal spaces being either effaced, or rising beyond the level of the ribs. In these spaces fluctuation can sometimes be detected. Change in

the form and dimensions of the side has been recognised as a diagnostic sign of pleuritic effusion since the dawn of pathology.

[The increased size, induced by effusion into the chest, is observable early; — Laennec says after two days' duration of the disease,—Andral says, on the fourth or fifth day. The writer's observation, as stated elsewhere, (*Practice of Medicine*, 2d edit. i. 389,) would lead him to fix the appearance of this phenomenon at a later period. It has been usually considered, that protrusion of the intercostal spaces is always coexistent. But this, as remarked by Dr. Stokes, (*On Diseases of the Chest*, 2d Amer. edit. p. 466, Philad. 1844,) may be wanting. Moreover, dilatation of the side may be absent, where even copious effusion exists, owing to the displacement of the diaphragm. The observer in making these comparisons must bear in mind, that the right side, in health, is often larger than the left. The average result of the most accurate admeasurements of 20 chests of persons not labouring under disease of the lungs gave, according to Dr. Stokes, for the right side, 17.86 inches, and for the left 17.23,—or more than half an inch in favour of the right lung. Of these, the most capacious chest measured 22 inches for the right, and 21.50 for the left. In one case only, the left side was larger than the right; and in three the sides were symmetrical. In the case in which the left side was more developed, the man was left-handed. In the work already cited, the writer has given the admeasurements of ten males and ten females, taken by himself or under his inspection—none of the individuals labouring under disease of the lungs. The average of these gave 16.92 inches for the left side, and 17.47 inches for the right in the male,—being a difference of about half an inch; 15.1 inches for the left side, and 15.2 for the right in the female,—being a difference of not more than one-tenth of an inch.]

When the effusion is on the left side it will have the effect of displacing the heart, and of causing its pulsations to be heard either on the right side or in the epigastrium; hence, if we miss the heart in its normal position, and perceive its action in either of these situations, we have very strong grounds to suspect, if not conclusive evidence of, this lesion. [See article Empyema.]

M. Reynaud has suggested a mode of ascertaining the existence of fluid effused into the chest, which consists in the application of the hand to the side where the effusion is suspected, and then making the individual speak, when the effused fluid will be found to interrupt the vibrations which the voice communicates to the walls of the chest when the lungs are sound.

[By placing a hand under each scapula, pleuritic effusion may, in this manner, be detected. Dr. Stokes, (*Op. cit.* p. 462,) regarded this sign as of far greater value than egophony. It does not exist, however, in many cases of females and of boys prior to the change of voice,—the vocal vibrations in them, although audible, not being sufficiently powerful to be felt by the hand.

The pectoriloquism of phthisis, and the egophony of pleurisy are regarded as the least valuable of the physical signs of these diseases; still, the presence of egophony with dulness on percussion, enfeebled respiratory murmur of the affected side, with absence of the crepitant rhonchus, and of the vibratory vocal fremitus, would be a strong combination of evidence in favour of the existence of pleurisy.]

Varieties of Acute Pleurisy.—Acute pleurisy may be double, that is, it may involve both sides of the chest at the same moment. This is by no means a common occurrence, and when it does take place, and is speedily followed by extensive effusion into both sides, the sudden and extensive mechanical interference with the function of respiration soon extinguishes life. Percussion affords us no assistance in forming our diagnosis in this case; for as we have no absolute standard of the degree of resonance which it should yield, it is by comparison of the two sides that we can alone judge; but the effusion, producing a dull sound in both sides, deprives us of the value of this physical sign. However, if we keep in mind the observations we before made upon the differences between pleurisy and pneumonia, and apply them to the subject under consideration, we shall have little difficulty in identifying this affection, and distinguishing it from the only modification of disease with which it could by possibility be confounded. Double pleurisy, but of inconsiderable extent, often takes place in the agony of acute diseases.

Partial or circumscribed inflammations of the pleura are very common. They in general produce no fever or constitutional disturbance, and are only announced by a pain more or less acute in some point of the walls of the thorax: the pain too is not a constant symptom. A slight exudation of lymph takes place, and this, in the course of time, is transformed into a cellular band. This is the history of those cellular adhesions which unite the pluræ pulmonalis and costalis more or less intimately. These adhesions have often been found in persons who, during life, never gave reason to suspect any affection of the chest. Although these partial pleurisies may exist alone, they more frequently occur in cases of affection of the pulmonary parenchyma. Phthisis pulmonalis is their most fertile source, and hence arise the frequent pains in different points of the side, of which the subjects of this disease so often complain. These painful points bespeak inflammation of the corresponding portions of the pleura, and in our subsequent examinations we find adhesive cellular bands in these situations. The number of these adhesive bands is, in general, in the direct ratio of the number of tubercles, and they exist particularly in points corresponding to those where the tubercles are most abundant: hence their most constant situation is between the apex of the lung and the summit of the cavity of the chest; the adhesion here is sometimes so firm as to defy our utmost efforts to break it.

Some partial pleurisies demand peculiar attention in consequence of the particular symptoms to which they give rise. Inflammation of that portion of the pleura which lines the diaphragm claims our especial consideration upon this score. Its characteristic features are, in addition to the ordinary constitutional symptoms of acute pleurisy, pain more or less acute of the cartilaginous border of the false ribs, extending into the hypochondria, and even to the flanks; complete immobility

of the diaphragm in inspiration, which is performed by the elevation of the ribs; orthopnœa, with an inclination of the body forwards; an inexpressible anxiety of countenance, marked by a sudden change of features; the respiration more hurried and jerky than in ordinary pleurisy; the voice low and interrupted, (entre-coupée;) a frequent desire to cough, but an obvious dread of it from the pain which it causes. The intellect is free at first, but when the case is aggravated, and the constitutional symptoms run high, delirium comes on. In addition to the symptoms enumerated, we have the ordinary physical signs of pleurisy; viz. in the first moments of the disease, if the pain will allow us to employ percussion, we find a disproportion between the sound it yields in the inferior part of the chest, and the distinctness with which respiration is heard in this situation, the latter being feeble while the former is clear; in the course of a short time the sound here becomes dull, and the respiratory murmur ceases to be heard, and these two phenomena extend upwards in proportion to the extent of the disease. When the effusion takes place into the right cavity of the pleura, it presses down the liver, and causes it to be felt below the margin of the ribs; when it takes place into the left cavity, it produces a similar change in the position of the spleen. The signs which we have just enumerated may be regarded as the most constant and unequivocal of diaphragmatic pleurisy; others are occasionally present, viz. hiccough, nausea, vomiting, jaundice, &c. It was the presence of jaundice that led Valsalva to regard the accidental complication as the original disease; a mistake which might naturally occur, if, as happens in many cases, the features of the preceding pleurisy had not been strongly marked. The risus sardonicus, to which the ancients attributed so much importance as characteristic of this modification of disease, has not been found constant by modern observers.

There is a partial pleurisy which claims our attention, in order to guard against a pathological error into which we might fall did we not conduct our investigation with care. We allude to interlobular pleurisy, in which the cellular membrane, the result of the present or of a former inflammation, connecting the lobes of the lung, may become the nidus of an abscess, which a superficial observer might easily mistake for an abscess in the substance of the organ.

It is almost superfluous to observe that partial pleurisies owe their importance to the extent of surface which they occupy: the more extensive they are, the more serious are the consequences. Preceding pleurisies, in which adhesions have been formed, limit the extent of future attacks; these adhesions, as it were, divide the cavity of the pleura into smaller cavities, and thus circumscribe future pleurisies.

Inflammation may affect either the costal pleura alone, or the pulmonary pleura, or both at the same moment. In the first case, it is not always easy to determine whether the affection be rheumatism of the intercostal muscles, or inflammation of the costal pleura; we have in each the same pain produced by the same causes, and the same modification of respiration, in the performance of which the ribs seem to take no share. When the pulmonary pleura alone is affected, the pain is produced by the air inspired stretching this membrane, and it is the effort to avoid this that gives the short hurried character to the respiration.

There is a neuralgic pain of the side which is sometimes mistaken for inflammation of the pleura, but which differs from it in being unaccompanied with fever, and in the character of the pain, which is represented as a burning or scalding sensation, and not as a sharp lancinating pain. The neuralgic pain differs from the pleuritic in being relieved by pressure.

Causes of Acute Pleurisy.—These may be divided into the predisposing causes and the occasional or exciting causes. Among the first may be enumerated congenital malformation, consisting in narrowness of the chest; a sanguine temperament; irritability of the system; weakened health from previous disease; convalescence from fever; the puerperal state. The exciting causes embrace all mechanical injuries directly applied to the pleura; such as contusions, penetrating wounds caused either by cutting instruments,* or by sharp spiculæ of fractured ribs; extension of ulceration from a softened tubercle in the substance of the lung perforating the pleura, and giving rise to a complication to which we shall have occasion to advert; cold applied to the surface when the cutaneous capillaries are in a state of excited action, &c. The mode of operation of the cause last mentioned is supposed to be by directing the fluids from the circumference to the centre, and thus determining their afflux to the serous membrane; and as this cause has also the effect of producing a congestion of the parenchyma of the lung, and, in consequence, a tension and stretching of the investing pleura, it was supposed that in this way it contributed to produce pleurisy. The frequent complication of intermittent fever with pleurisy further countenanced this idea. However, we cannot but consider the rationale of this cause as too mechanical, and would rather connect it with some physiological sympathy existing between the skin and serous membrane of the chest. Pleurisy is often found to depend upon a certain *intemperies* of the atmosphere, which causes an epidemic spread of the disease; and like all epidemics, it then assumes a less sthenic type than isolated sporadic cases do; in this modification of the disease, the digestive apparatus is much deranged, and hence it has been designated *bilious pleurisy*. Metastasis of gout or rheumatism, or a repressed cutaneous eruption, may be the exciting causes of acute pleurisy. Pneumonia, by an extension of inflammation, so often induces pleurisy, that, as we before observed, it was long thought that they could not exist independent of each other. While pathology has controverted this error, it has shown us that pneumonia more frequently produces pleurisy than pleurisy produces pneumonia.

Pleurisy is said to be *latent* when it exists unannounced by the ordinary symptoms which usually accompany it, such as pain of the side, hurried respiration, dry cough, &c. We have observed pleurisy supervene in this insidious way

* We have seen a fatal case of pleurisy produced by perforation of the pleura in passing the needle round the subclavian artery for the cure of aneurism of this artery.

in the convalescence from fever: the patient, after having made some advance towards recovery, is observed to fall back again; he makes no complaint of his chest; still on careful examination we observe a slight hurry of the respiration, and hear an occasional dry cough; these direct our attention to the chest, where we find unequivocal evidence of pleurisy with effusion.

Complications of Acute Pleurisy with other diseases.—We may premise that acute pleurisy is much oftener simple and uncomplicated than chronic pleurisy. The frequency of the coincidence of acute pleurisy and pneumonia (*pleuropneumonia*) claims the first place in the enumeration of the complications of acute pleurisy. The pneumonia may be either the cause of the pleurisy, or it may be the consequence of it; or these two diseases may commence at the same moment, being the independent effects of the same morbid impression. In general, in pneumonia, when the inflammation reaches the surface of the lung, the contiguous portion of the pleura becomes inflamed, and is coated with a layer of lymph, usually thin, and often an exact measure of the extent of the inflammation of the lung. When the entire lung becomes hepatized, we have often observed the whole investing serous membrane covered with a more or less dense false membrane, marked with parallel lines produced by the impression of the ribs upon it. This complication exhibits the most common case of what has been termed *dry pleurisy*. We need hardly observe that the pleurisy here is of very subordinate importance: it is that, however, of which the diagnosis would embarrass us most, had we not seen the case at its commencement. The pressure of the effused fluid may have the effect of exciting inflammation in the lung: the ordinary stethoscopic phenomena will disclose this complication. The inflammation seldom goes beyond the first stage of pneumonia; and from the repeated opportunities we have had of examining the bodies of those who died with pleuritic effusion, and the few specimens we have seen of pneumonia in the compressed lung, we believe this complication to be very rare, and suspect that the carnified condition of the lung has been not unfrequently mistaken for the first stage of pneumonia. Laennec remarks that the pressure of the fluid has rather the effect of placing the lung out of the pale of inflammation. The third complication, or pleuropneumonia properly so called, in which the proper tissue of the lung and its investing membrane are simultaneously affected, is recognised by its exhibiting the stethoscopic phenomena peculiar to each lesion. The case is not very much aggravated by the complication; Laennec even considers the danger less than if either existed alone in a more considerable degree; for he is of opinion, as we above stated, that the pressure of the fluid controls the pneumonia, and that, in return, the absorption of the effused fluid is promoted by its being compressed between the unyielding solidified lung and the sides of the chest. This is a case in which the fluid is interposed between the lung and the side of the chest, in consequence of the lung, from its increased density, not admitting of displacement.

We have before adverted to the frequency of the complication of pleurisy and tubercles in the lungs, in which case there generally existed adhesions between the pleuræ pulmonalis and costalis. However, it will happen that, in some instances, nature will seem as it were to neglect the precaution of establishing an adhesion between the opposite serous surfaces; and softened tubercles situated near the surface of the lung will, in obedience to the pathological principles of purulent matter seeking the easiest and shortest outlet, perforate the pleura, and immediately give rise to a most intense pleurisy, marked by a very acute pain of the side, most distressing difficulty of breathing, and extreme anxiety. When we come to examine the chest, we find all the physical signs which characterize pneumothorax with effusion, (vide Pneumothorax,) in which case we know the lesion to consist of pleurisy and a tubercular cavity into which a bronchial tube opens. It may happen that the softened tubercle perforating the pleura will only give rise to simple pleurisy, in consequence of its not communicating with a bronchial tube.

Gangrenous ulceration of the lung and pleura will cause either pneumothorax or pleurisy; in addition to their respective signs, the sputa and breath have an insupportable fetor.

Pleurisy of one side is not unfrequently complicated with some disease of the opposite lung, arising out of the increased duty that has devolved upon it. This lung may either become emphysematous, or the subject of bronchitis or pneumonia. It is frequently attacked with sudden congestion, which produces most urgent sense of suffocation, and renders the patient's situation truly pitiable. We have before alluded to the fact that when pleurisy of one side exists, it seldom involves the pleura of the opposite side, but leads either to pneumonia or bronchitis; and when pleurisy is double, there is a fair start between both sides, and their affections proceed *pari passu*.

Prognosis of Acute Pleurisy.—Pleurisy is ever a serious disease; in many cases, however, it terminates favourably. The danger is proportionate, 1st, to the cause upon which the disease depends: when it depends upon ulceration of a tubercle, or upon superficial gangrene of the lung, it is always fatal: 2d, to the extent of the inflammation: double pleurisy is attended with more danger than when the disease is confined to one side; and when the whole cavity of the pleura is inflamed, the prognosis is more unfavourable than when only part of it is affected: 3d, to the quantity and nature of the effusion: 4th, to the time during which the effusion has existed: 5th, to the diseases which complicate the inflammation of the pleura, or which exist along with it.

Previously to noticing the treatment of acute pleurisy, we shall give the history of the disease in a chronic state.

II. Chronic Pleurisy.—There are two distinct kinds of chronic pleurisy: one, the continuation, as it were, of the disease in its acute form; the other, to use the usual but paradoxical question, chronic from its commencement; that is to say, at no period exhibiting either the intense fever, the acute pain, or energy of reaction which characterize an acute disease. When the diag-

nosis of diseases of the chest was less certain than it has been since the acquisition of the stethoscope, the first form of chronic pleurisy was much more common than it is at present, for this reason,—that formerly being without the means of appreciating the physical signs of the disease, when the pain, the most prominent symptom, had yielded to antiphlogistic means, it was then conceived that the inflammation was subdued and the cure complete; the patient then returning to his former diet and resuming his usual occupations, was often surprised by an attack more violent than the former. Our improved mode of examination teaches us that every symptom of inflammation may have disappeared, every function apparently be restored to its natural condition, and still there may be considerable effusion into the cavity of the chest: until this be entirely removed, we never can feel secure about our patient. Pleurisy, in its essential chronic form, creeps on very insidiously, without much acceleration of pulse or heat of skin; and when there is any *unusual* sensation in the side, it does not amount to more than a mere soreness: the difficulty or hurry of breathing is sometimes so inconsiderable as not to attract the individual's attention. An observer is struck with the patient's unhealthy pallid appearance; there is a loss of appetite and a languid look, which emphatically tells us of some mischief going on; on close examination we find that the absence of fever is not constant, but that towards evening there is a febrile movement. A dry cough, or one attended with scanty mucous expectoration, and which has existed a considerable time without any apparent dependence either upon crude tubercles in the lungs or upon gastro-intestinal irritation, should lead us to suspect the possibility of chronic pleurisy.

The anatomical characters of chronic pleurisy do not differ very widely from those of the acute form, especially when it has been a mere transition of one form of the disease into the other. In this latter case, no matter to how distant a period the disease may be protracted, the fluid effused retains to the last its primitive character. As in acute pleurisy, it is a straw-coloured serum, but more consistent, apparently owing to its holding in suspension a considerable portion of the fragments of the false membrane, which, on the fluid settling, sink to the bottom. These condensed fragments, which, on opening the chest, are found in its most dependent parts, constitute, according to Laennec, a connecting link between the sero-purulent effusion and the false membrane. In essentially chronic pleurisy the effusion partakes more of a purulent character: in this case the disease closely resembles an abscess, the false membrane investing the pleura corresponding to the cyst, and endowed with the physiological properties of absorption and secretion. If the constitution be imbued with a scrofulous taint, (which is the habit in which we most frequently meet with this morbid condition,) the effusion will exhibit the ordinary characters of scrofulous pus, viz. a thin, whey-coloured matter, with flocculi of lymph floating in it. When the effusion is mainly purulent matter, mixed with a small proportion of serum, it is of a greenish colour, and very much resembles an effusion of tea to which a small proportion of milk has been added. The effusion in chronic pleurisy is not as exempt from smell as that in the acute disease.

The false membrane in chronic pleurisy is not essentially different from that in acute pleurisy; it is only firmer and more condensed, owing, perhaps, to the longer time it has been under the pressure of the effused fluid. It is capable of all the transformations of which we stated it to be susceptible in acute pleurisy; and to its conversion into fibro-cartilage, Laennec ascribes a particular change in the configuration of the chest, to which we shall presently have occasion to advert. It is more prone than in acute pleurisy to become the matrix of morbid developments, especially tubercle.

The lung is more compressed than in acute pleurisy; it is often reduced to a thin lamina, not exceeding six lines in thickness, lying down along the spine. There is also a more complete annihilation of its vesicular structure. It was this condition of the organ that led less careful examiners to pronounce upon its entire removal. Tubercles or other morbid growths may develop themselves in it, and, undergoing their proper changes, modify the symptoms of the original disorder.

Diagnosis of Chronic Pleurisy. — The physical signs of chronic pleurisy differ little from those of acute, except in being more prominently expressed; and apparently for this reason,—that the disease, from its insidious character, has excited little constitutional alarm, and therefore the individual labouring under it has unconsciously permitted it to go on without seeking medical relief. In general, then, when it presents itself to the physician it has existed for a considerable time. The affected side is more rounded; the intercostal spaces are more dilated, and raised above their natural level, in some cases admitting of fluctuation being felt; the integuments of the side often become œdematous. When the disease has existed for a long time, the spine is observed to deviate from its natural direction, and to form a curve with its cavity looking towards the affected side. If the left side be the seat of the effusion, the heart undergoes the same displacement as in acute pleurisy.

The œdematous state of the integuments lessens, at least, the value of percussion as a means of assisting our diagnosis. There is not only a more complete absence of respiratory murmur, but not even ægophony or bronchial respiration is present. Double chronic pleurisy is a very rare form of disease.

Partial or circumscribed chronic pleurisy is more frequently met with than the same modification of acute pleurisy; and although there are many circumstances connected with it calculated to embarrass the diagnosis between it and pneumonia, especially our seldom having an opportunity of observing it *ab initio*, still the marked expression of the physical signs seldom leaves us at fault. It sometimes happens that the circumscribed nature of the affection shows itself to the eye by a distinct line of demarcation intersecting the side of the chest. If it happens that the pleurisy occupies the inferior part of the side, (which is most frequently the case,) below this

line will be found the physical signs of pleurisy, with dulness of sound and absence of respiration; while above it, the only deviation from the ordinary state of things is puerile respiration.

Pleurisy assuming a chronic character from its commencement generally occurs in a cachectic habit of body, or where the health has been broken down by previous illness. We have met with it more than once after fever, and usually either in scrofulous habits, or in persons much addicted to intemperance.

Prognosis of Chronic Pleurisy. — The prognosis of chronic pleurisy is, generally speaking, very unpromising; however, if it exist as an isolated affection, apart from any complication, it may go on for months, nay, for years. If, as is often the case, tubercles form and go through their changes either in the compressed or in the opposite lung, the complication will have the effect of precipitating the fatal termination. In the ordinary course of the disease, a slow, wasting fever sets in; there is a gradual emaciation; the appetite fails; the pulse is languid, although not much quickened; the legs swell, and the face becomes puffed; the expectoration often has a disagreeable alliaceous smell. Upon these symptoms well-defined hectic fever soon supervenes, and rapidly wears down the patient.

Nature often takes the cure of pleurisy into her own hands, and seeks to relieve herself of the fluid effused into the chest in one of the following ways: 1, by absorption; or, 2, when the fluid is purulent, by making a passage for it through the pulmonary tissue into a bronchial tube, from whence it is expectorated; or though the walls of the chest, from whence it flows immediately out; or in some cases she adopts these two last ways at the same moment.

When the disease has existed a long time, and nature at length takes upon herself a slow, gradual process of absorption, which she takes a considerable time to complete, we observe that remarkable change in the form of the side to which we before made allusion: this side, which was before perceptibly longer than the opposite one, now becomes less; it is diminished in all its diameters, its circumference sometimes measuring less by an inch than that of the opposite side. Its length is not less encroached upon; the ribs are approximated, the shoulder becomes lower, and even the spine, in some cases, assumes a lateral inclination from the habitually bent position of the patient. The muscles of the chest, especially the great pectoral, seem to have lost half their volume. We shall easily comprehend the nature of this change, when we reflect upon the cause upon which it depends. Laennec, who was the first to notice it, charged it upon the fibro-cartilaginous nature of the false membrane, which continued to oppose itself to the lung's being restored to its original condition: it interfered with its vesicular texture so as to render it impervious to the air: the organ had, in fact, virtually undergone a change of dimensions, in consequence of which the relation between it and its containing cavity was lost. The atmospheric pressure acting upon the side, and not counterpoised from within, causes it, as it were, to fall in and accommodate itself to the altered condition of the lung. We cease to wonder that the unyielding bony case should have its form influenced by this condition of the lung, when we reflect how speedily an opposite state, or dilatation, will succeed to an emphysematous condition of the contained organ. A cause mainly instrumental in the contraction of the side is the atrophy of the muscles from disease, respiration being exclusively carried on by the opposite side.

When nature relieves herself of the accumulated fluid by a passage through the pulmonary tissue into a bronchial tube, the individual, who has been for some time labouring under either a dry cough, or one attended with scanty discharge, is suddenly seized with an abundant expectoration of greenish, purulent matter, which comes forth with such a gush as to appear to be vomited rather than expectorated. The discharge from the lungs continues from day to day, the quantity gradually diminishing till it ceases altogether. In proportion as the matter is discharged, we perceive the fulness of the side to give way, and to come down to its normal dimensions. In this case a considerable time will elapse before percussion and auscultation yield their natural results, the sound continuing dull, and respiration feeble; still the function of the lung will ultimately be restored, differing from the case of contraction of the side, in which the dull sound and feeble respiration are permanent.

The third expedient which nature adopts for the discharge of the purulent fluid in the chest is to give the pleurisy the character of an abscess, making its way through the walls of the chest, and pointing externally. When the apparently small abscess on the side of the chest either opens spontaneously, or is opened by art, it discharges a quantity of matter quite disproportionate to its size, and this matter is pumped out at each expiration and cough. Sometimes the matter gets vent both through a bronchial tube and through the side of the chest at the same time. It is a singular fact, that when the fluid in the chest is discharged through the lung, and consequently through a communication established between a bronchial tube and the cavity of the pleura, pneumothorax does not ensue, although it is previously the same lesion that gives rise to this morbid phenomenon; the difference being only in the mode in which this lesion takes place.

Treatment of Pleurisy.—If the energy and activity of our practice in the phlegmasiæ should be in proportion to the importance of the part inflamed, there is scarcely any part in the whole animal machine in which the inflammation demands a more decided and uncompromising plan of treatment than the pleura. If we temporize in the treatment of pleurisy, the least evil we can anticipate is a protracted convalescence; whereas if we meet it, *in limine*, with vigour, we often, as it were, strangle it in the birth.

I. **Treatment of Acute Pleurisy.** — The treatment of acute pleurisy comprises all the means usually employed to reduce constitutional fever and local inflammation.

Bloodletting.—In the first stage of the disease, when febrile excitement runs high, and is accompanied with much local distress, we should bleed with an unsparing hand from a large orifice, and in the manner most calculated to make the speed

iest impression upon the system. Should a single bleeding, conducted in this way, fail to afford very decided relief, we should resort to the operation again within a few hours, and repeat it at more or less distant intervals, according to the urgency of the symptoms and the capability of our patient to bear further loss of blood. Some have attempted to fix the precise quantity of blood to be drawn in the cure of a pleurisy; a generalization to which nature will not submit, the effects of bleeding differing in different individuals. It would be to trust to a very fallible guide, indeed, were we to depend upon the indications of *the pulse*. In this, as well as in the inflammation of all other serous membranes, the pulse, so to speak, as often underrates as exaggerates the extent of the mischief, being rather a measure of the constitutional irritability of the individual than of the actual amount of disease. The usually accompanying *pain* is a symptom upon which we can place more reliance, and the effects produced upon it serve, in some measure, to guide us as to the extent of depletion; but even it, so far from being proportionate to the extent or intensity of the inflammation, is often absent when the inflammation occupies a considerable extent of surface; and even when both sides are affected at the same moment, if it be present, it is often found not to amount to more than a mere soreness. The *dyspnœa*, or rather the nervous dread of drawing in a full breath, in many cases lasts for so short a time, that we must see the patient in the first moments of the attack to have the value of this symptom. Were we to lay down any general rule, deduced from the common symptoms, as to the limit to which we would carry sanguineous depletion, we should be most disposed to regulate this by the strength of the patient, and the relief of the pain and consequent power of taking in a full inspiration.

While we distrust the indications of the pulse, which, in some cases, from its composure, is calculated to mislead us as to the expediency or necessity of bleeding, so we should be equally on our guard not to be betrayed into the opposite error of considering an accelerated pulse, which may be produced by the depletion we have employed, as the index of continuing inflammation, and be thus led to push depletion still farther, and thereby originate functional disorder ultimately terminating in organic disease of the heart. We have seen this mistake so often committed, that we deem it necessary to subjoin this caution.

While we employ general bleeding, we may at the same time seek to relieve the local congestion by cupping and leeching. In the necessarily protracted operation of topical bleeding, we should manage it with caution, so as not to run the risk of exposing our patient to cold. Venesection does not seem to be equally applicable to every modification of pleurisy. Thus, when it prevails as an epidemic, or develops itself in the progress of fever, or occurs as a puerperal disease,—in all these instances it assumes an asthenic type, when it becomes very questionable if general bleeding be at all admissible, or if we should not rather confine ourselves to local bleeding, with such other resources as art affords. This at least is certain, that in these cases bleeding should be employed with extreme caution. In circumscribed pleurisy, with which the constitution does not seem to sympathise, the application of a few leeches to the seat of the pain will often remove all uneasiness. If, as in phthisis, in which partial pleurisy is so common, the exhausted state of our patient will not bear even so small an abstraction of blood, the temporary application of a hot turpentine stupe will often answer our wishes.

Purgatives.—The saline purgatives are especially suited to this first stage of pleurisy, as they diminish the mass of the circulating fluid by greatly increasing the secretion of the intestinal mucous surface. We follow up this antiphlogistic treatment by other means calculated to reduce fever, by producing diaphoresis, or otherwise, viz. the different preparations of antimony, tartar-emetic in very minute doses, James's powder, Dover's powder, &c.

Sedatives.—These are often very useful in quieting the irritation of the cough, and thus procuring the repose of the organ affected. With such a view we derive much benefit from the use of hyoscyamus, conium, lactucarium, &c. Some recommend the use of opium in large doses after bleeding, by which we continue, as it were, the sedative impression of the bleeding, as well as allay the irritation produced by the pain, and soothe the cough.

Mercury.—The combination of calomel and opium enjoys an established celebrity in the inflammations of serous membranes; and after the use of venesection, and where there exists much pain, the remedy is invaluable. In such cases, our object is to bring the system as speedily as possible under the influence of mercury, by which we as it were supersede the morbid action which is going forward.

The treatment which we have just laid down applies to the earliest stage of pleurisy. However, it often happens that the patient does not present himself till the disease has existed at least for some days, and the intensity of the symptoms has in some degree abated, when the inflammation has assumed rather a subacute character, and has partly terminated in effusion. It is now that we have most reason to complain of the pulse not intimating to us the extent of the mischief. We now come to the long agitated question,—how late in the progress of pleurisy are we warranted in using the lancet? Without attempting to lay down a general rule upon the point, we would say that even now, notwithstanding the tranquillity of the pulse which often exists, we expect decided advantage from bleeding, inasmuch as we thereby, 1. check the further effusion of fluid; 2. promote the removal of the fluid already effused, by increasing the powers of the absorbing system at the expense of the circulation; 3. render the system more susceptible of the influence of the medicines we employ.

When the inflammation has nearly subsided, and the acute pain given way to a mere sensation of soreness, and we have the physical evidences of effusion, the indications of cure now are different, our main object being to promote the removal of the effused fluid. The means we employ for this purpose are either internal or external; the former comprising those medicines which,

acting by way of derivation either upon the kidneys or bowels, thus indirectly affect the effusion; the latter comprehending the different modifications of counter-irritation, which, by stimulating the absorbents, tend to produce the same effect more directly.

Diuretics.—The popular combination of squill, digitalis, and calomel, produces as speedy a diuretic effect as any we can employ. Laennec speaks highly of the infusion of digitalis from experience of its value in the particular case under consideration. It recommends itself to our notice upon the double grounds of its diuretic property and the control it exercises over the circulation; an important recommendation, when we consider the proximity of the organ affected to the source of the circulation, and the advantage from the blood being driven into it with diminished impetus. We may also employ, separately or in conjunction with the above, the saline diuretics, viz. the nitrate, acetate, and bitartrate of potash.

Purgatives.—If the strength of the patient will permit, we may make use of the hydragogue cathartics, viz. elaterium, jalap, scammony, camboge, &c.; but the operation of these medicines is attended with so much exhaustion, that we can only employ them occasionally.

Diaphoretic medicines afford us such very feeble assistance at this stage of the disease, that they scarcely deserve a place among our remedial agents. We have not found tartar-emetic to sustain its character of an active antiphlogistic agent in uncomplicated acute pleurisy; but when the lung is involved in the same inflammation, we then find the advantage of associating it with our remedies.

When we are endeavouring to affect the system with mercury administered internally, we may at the same time employ mercurial friction on the side, by which we assist the internal exhibition of the mineral, while we stimulate the absorbents.

Stimulating liniments carry with them the advantages that we can regulate their irritating property *ad libitum*, and that they do not unfit the surface to which they are applied for any future application.

When the milder counter-irritants, as auxiliaries to the internal means employed, have failed to make any impression upon the fluid, we resort to blisters. Andral's work (Sur les Maladies du Poitrine) abounds in cases in which the removal of the fluid seemed to date itself from the application of a blister. A succession of blisters acts more effectively than a single one of which the discharge is continued by an irritating application.

As long as fever and inflammation are present, we of course insist upon rigid abstinence. But when these have subsided, and have left their effects alone behind them, the reasons for continuing the same strict system are scarcely less cogent; for in this way we lower the circulation, and thus establish a physiological ratio between its powers and those of the absorbing system, whereby the latter are much increased, and act with much more avidity upon the fluid in the chest. We find it extremely difficult to carry this part of our treatment into effect; for our patient will regain a degree of health, and feel very little if any inconvenience from the fluid in the chest, and not being able to reconcile our severe restrictions with his sensible amendment, will become impatient of restraint, and, yielding to his improved appetite, will in all probability bring on fresh inflammation.

Sometimes a considerable time will elapse before any impression is made on the fluid, the system seeming as it were to stand out against the operation of our remedial agents up to a certain point, and then suddenly yielding, its removal rapidly ensues. At other times our medicines begin to take effect quickly, and remove the fluid gradually. We recognise the effects of our remedies by the side losing its fulness, by the reappearance of ægophony,* by the return of the respiratory murmur and clear sound to situations where we before sought them in vain. Percussion will continue to yield a dull sound for a considerable time after the return of the respiratory murmur.

It seldom happens that in acute pleurisy we have to resort to the operation of *paracentesis thoracis;* nor should we ever think of it as long as we have any prospect of removing the fluid otherwise; still it may happen, from the other lung becoming affected either with bronchitis or pneumonia, or from having been already emphysematous, that to relieve the urgent sense of suffocation we have no alternative. In almost all these cases we find the operation to be attended with no more than a mere temporary relief, the fluid soon collecting again. It is an ascertained fact that the operation is, in general, less successful in acute than in chronic pleurisy, the reasons for which we shall endeavour to explain when we come to speak of the treatment applicable to the latter form of the disease.

I. **Treatment of Chronic Pleurisy.** — The treatment of chronic pleurisy, or of that modification of the disease which from its commencement exhibits some of the characteristics of an acute inflammation, is as different from that of acute pleurisy as the respective natures of the two forms of the disease. Antiphlogistic means, whose activity is measured by the intensity of the febrile symptoms and the strength of the individual, constitute the treatment of acute pleurisy; and amongst these means, bleeding, as we have seen, occupies a most prominent place. In essentially chronic pleurisy, we seldom, if ever, have occasion to resort to constitutional bleeding. The weakened, if not the vitiated habit of body in which it generally takes place, will not admit of the exhaustion which this operation would produce; even local bleeding must be employed with considerable caution. The indications of cure are, to remove the fluid from the cavity of the chest, and to improve the dilapidated state of the system. The means by which we try to promote the removal of the fluid may be divided into constitutional and local; the former comprising those agents whose action is directed to some organ or set of organs at a distance from the seat of disease, and which effect the object we contemplate by establishing a counter-irritation and increased secretion at the expense of the diseased secretion, which continues to take

* This effect was ascribed by Laennec to the transmission of the voice through a diminished stratum of fluid; but we consider it to be rather due to a less compressed state of the lung from the diminution of the compressing fluid.

place into the chest until it is as it were superseded.

Most of the means which we adverted to as applicable to the stage of acute pleurisy when effusion has taken place, may be seasonably employed in chronic pleurisy, qualified alone by the consideration that in the latter form of the disease the habit of body in general is not such as will bear the operation of active medical agents. When we employ mercury, we must manage its exhibition with caution, and beware lest, in pushing its use too far, we give rise to an irritative fever, which would soon exhaust the weakened constitution in which this modification of pleurisy usually presents itself: we should content ourselves with slightly affecting the gums. When hectic symptoms show themselves, we should cautiously abstain from the use of mercury altogether. We employ the same diuretics as in the second stage of acute pleurisy. We cannot, without incurring the risk of weakening our patient too much, resort to active purgation; we must, therefore, be satisfied with the mildest medicines of this class, and those whose operation draws least upon the stamina, viz. castor oil, manna, &c. Diaphoretic medicines lend us more aid in this than in the second stage of acute pleurisy; for instance, Dover's powder, James's powder, &c.

Constitutional means or internal medicines, we must in candour admit, do not assist very much in the removal of the fluid.

[Iodine has been highly extolled, employed both internally and externally. Dr. Stokes (*Op. cit.*) advises, that Lugol's solution should be taken freely; and that from a quarter to half an ounce of the compound iodine ointment should be rubbed daily over the side. By others, the use of iodide of potassium is preferred, and, in more asthenic cases, iodide of iron.]

The external applications, and upon which we place our principal reliance, comprehend the different modifications of counter-irritation, viz. blisters, setons, issues, stimulating liniments, &c. Blisters are unequivocally the means most calculated to promote the absorption of the fluid secreted into the chest, as well as to interfere with its further secretion. We employ a blister commensurate with the extent of surface involved in the inflammation, and repeat its application in preference to keeping the blistered surface open by means of irritating substances, each repetition having as it were the effect of renewing the counter-irritation.

The next part of the treatment of chronic pleurisy regards the improvement of the habit of body and relief of the constitutional symptoms which most commonly accompany this form of the disease. We are not obliged to prescribe the same restricted diet as in acute pleurisy, but would admit a certain latitude, always taking care to avoid such substances as are calculated to produce febrile excitement, and consequent acceleration of the circulation; for, as we before observed, the powers of absorption and circulation observe an inverse ratio, and as we require the efforts of the former to remove the fluid, we should defeat our object did we not observe this caution. It is, besides, an object of importance that as little blood as possible should be transmitted through the lung lying under the pressure of the fluid. In many cases chronic pleurisy is attended with such slight constitutional symptoms as scarcely to deserve to be considered more than a local disease; still in most instances hectic fever sooner or later sets in. At this stage of the disease, change of air is productive of the most decided benefit, often effecting an almost instantaneous amelioration in the symptoms: the night perspirations cease, the appetite improves, and sleep becomes refreshing. In the exhibition of tonics we have had reason to prefer the infusion or decoction of bark, combined with sulphuric acid, to the more concentrated sulphate of quinine. We have found much advantage, in these and similar cases, from the mineral acids in decoction of Iceland moss. When our curative means take effect, we recognise their success by the physical signs of the disease gradually disappearing; by the side losing its fulness; by the intercostal spaces sinking down to their ordinary level, and being less dilated; and by the return of a feeble respiratory murmur, and a less dull sound on percussion; and, in case of the left side having been the seat of the disease, by the heart's pulsation being felt in their normal situation; and by the liver ceasing to be felt below the margin of the right false ribs when the disease has occupied this side. But when, instead of these evidences of the efficacy of our means, we find the fluid to increase, and all the sensible signs of the disease more marked, and in consequence the dyspnœa more distressing, the operation of tapping the chest is our last and only resource. We must confess that the results that have usually attended this operation are far from being calculated to inspire us with encouraging anticipations, (see Empyema;) still even the few cases in which either complete recovery or relief for a considerable time has followed it, prevent us from despairing. It is impossible to judge what might be the event were the operation undertaken earlier; this must be a matter of conjecture, as we must ever look upon an operation, the unavoidable consequence of which is the admission of air into the inflamed cavity of the chest, as a serious matter, and only warranted by the failure of other means to produce the object we desire. We have similar effects produced in chronic abscesses when opened. As long as they had no communication with the air, so long they produced no constitutional disturbance; but no sooner is the air admitted than hectic symptoms quickly supervene. The cavity of the chest affected with chronic inflammation resembles a chronic abscess, both in its physiological and pathological conditions. The failure of success of the operation for empyema may be ascribed to the following causes;—to the irritative fever which often follows immediately upon the operation; or to the condition of the lung, occupied by tubercles in different stages, and giving rise to constitutional symptoms; or to the lung having been so long pressed upon by the fluid as to render its natural elasticity quite irrecoverable. We have before observed that the operation, undertaken under the most auspicious circumstances, is not exempt from a certain share of danger.

[It must be borne in mind, too, that twenty cases of complete and permanent recovery from empyema, by absorption, have been recorded by

one author, Dr. Stokes (*Op. cit.* p. 481), so that, as he properly remarks, the probability of a cure, and the efficacy of remedies, is much greater than has been supposed.]

We now come to consider if there be any case so hopeless and desperate that we can promise ourselves no advantage from the operation: if such case there be, it is when there is extensive tubercular development in the compressed lung; but even here Laennec does not hesitate to recommend the operation, from his conviction of the curability of phthisis even when there exists unequivocal evidence of a cavity in the lung.

Mr. Crompton has had considerable experience of the operation for empyema and its results; and of ten cases upon which he has operated, three have been attended with complete success. After operation, his practice is to inject a weak solution of chloride of lime, which he finds to have the effect of diminishing the discharge and of correcting its character. (See Empyema.)

We have remarked that the operation of tapping the chest is more likely to be successful in chronic than in acute pleurisy; that is to say, if an untoward combination of circumstances demands operation in the early stage of acute pleurisy, such operation is more uncertain in its result than the same operation undertaken in chronic pleurisy at a period equally distant from its commencement. This fact, established by experience, we would account for in one of two ways; either that the constitution sympathises less, or suffers less irritation from the admission of air into the cavity of the chest, covered with a dense coating of lymph, as is the case in chronic pleurisy, than from letting in the same fluid upon the naked pleura unprovided with any such protection; or perhaps it may depend upon inferior susceptibility of inflammation in one case than in the other. In chronic pleurisy, the older the disease is, the less likely is the operation to be successful, because the more chance is there that the lung is disorganized; and the longer the lung has remained under pressure of the fluid, the less likely is it to recover its natural elasticity. The more circumscribed the pleurisy is, the more promising is the prospect of a successful operation.

For further information on the subject of the present article, we refer the reader to Empyema, Perforation, Pneumonia, and Pneumothorax.

Robert Law.

PLICA POLONICA, from *plico*, to knit together. This disease derives its name from the manner in which the hair is plaited or matted together, and, as its name also implies, is of most frequent occurrence in Poland. It has, however, been also observed in Tartary, among the Cossacks of Russia, in Hungary, and in a few instances in Switzerland and France. The people of Poland believe that it was carried into their country by the Tartars in the twelfth or thirteenth century. Schlegel, a physician practising in Moscow, who published a work on plica in 1806, gives a singular account of its origin. The Poles on the death of one of their kings, Miceslas II. in 1034, petitioned Pope Benedict the Ninth to release from his vows Casimir the son of Miceslas, who had entered into a convent of Benedictines in France; the request was granted on certain conditions, and one of the conditions required was, that from that time forward the men of Poland should keep their heads shaved. Casimir on his accession enforced the tonsure through all his dominions, and to the present day a part of the ceremony observed in assuming the national costume of Poland consists of shaving the head, a single tuft of hair being left to grow from the top of the scalp after the manner of the Tartar and some Indian tribes. The poorer inhabitants of Poland being wretchedly lodged and clothed, and exposed to the combined injurious influence of a marshy soil and a damp variable climate, the general cutaneous exhalation is at all times below the healthy standard, and the secretion from the scalp being still farther diminished by the custom of keeping the head shaved, there is, according to Schlegel, an increased compensating action thrown upon the bulbs of the hair which has been allowed to remain; and hence arises the greatly increased growth of this portion of the hair, and the unnatural quantity of viscid secretion which is at the same time thrown out.

The hair grows to a very unusual length, and being not only plaited but matted together by a viscid fatty secretion of an abominably fetid odour, resembling the stench of rancid fat, and in most instances crowded with vermin, presents an extremely disgusting picture of filth and disease. The hair of the scalp is that generally affected, but the disease is also seen in the axillæ, on the breast, and the pubes. In a few rare instances the nails are altered in their appearance, become livid or yellowish, long, and crooked, so as to resemble the talons of a bird of prey: this change is generally in the nails of the toes. The length which the hair sometimes attains is almost incredible. Cases are narrated of its reaching to the heels, of its being in such quantity and of such a length as to fall on the floor over all sides of the bed on which the patient lay. In the museum of Dresden there is a specimen preserved nine feet long. Not the least singular circumstance in the history of plica is the extraordinary attachment the Poles entertain for this dirty appendage. If the hair do not become spontaneously matted and filthy, the Poles spare no pains to make it so; the men put on dirty fur bonnets which have become coated with viscid secretion from being worn by others who laboured under the disease, or they interlace with their own hair masses of old plica steeped in beer! The women wear their hair very long, and, to encourage the growth of plica, refrain from combing it, and fasten it in knots, and make it adhere by glue or rosin. They will for years willingly suffer the greatest torture in carrying or dragging after them a mass of this matted hair, and beggars who are fortunate enough to possess a good plica cherish it with the greatest care as the most certain means of obtaining alms. In some parts of Poland the lower classes look upon plica as a special favour from Providence, which will preserve them from harm and sickness; in other parts it is viewed as an infliction coming from a malignant spirit, but not the less cherished, as it is then considered a protection from all other misfortunes. Lafontaine, a physician resident in Warsaw, who published a work on plica in 1792,

relates the case of a pregnant woman who had plica of four months growth on the pubes: during that period the urine was allowed to filter through the matted hair, and after labour commenced she could not be persuaded to permit the plica, which firmly resisted the protrusion of the child's head, to be incised, until her life was in the most imminent danger.

The prejudice in favour of plica is extended even to inferior animals. Horses presenting an appearance of the disease are valued beyond others, and hence the jockeys of Poland have learned to add another to the many arts practised by their brethren of other countries. It is said that in Poland, and in some parts of Russia, plica is occasionally observed in sheep, dogs, wolves, and foxes.

The physicians of Poland have not escaped the contagion of prejudice. Kerckhoff,* whose observations were made during the stay of the French army in Poland, relates a case illustrative of this. The patient, a boy of about fifteen years of age, complained of severe pains of his head. He lay in a most filthy state, and his black hair, knotted long and matted together, gave out an intolerable stench. The Polish physician in attendance strongly opposed Kerckhoff's suggestion of cutting off the hair, on the ground that the humour exuded on the hair might turn in on the brain and cause apoplexy. Kerckhoff entered into a compromise with the Polish doctor; and the hair was cut off in portions of two fingers' breadth at intervals of two and four days. In twenty days the whole scalp was cleared, and then, by simply keeping the head combed and washed, all the bad symptoms vanished.

Stories are related by some writers of the disease appearing very suddenly, and the hair preserving for years the particular form of dressing it possessed at the time of the seizure. These stories are, however, treated as fables by the best informed authors; and a statement generally made and believed in Poland, that the long hairs of plica are acutely sensible, and are the seat of great pain when touched, is equally void of foundation. In some instances the bulbs of the hair and the scalp are very sensible, owing to irritation, and pulling the hair ever so slightly gives acute pain; but Larrey and all modern observers positively assert that the hair may be cut at any part without causing the slightest pain, provided it be done without dragging the bulbs.

Pathology.—On the nature of plica the most opposite opinions are entertained. By some it is pronounced as a disease "sui generis," having its seat essentially in the bulbs of the hair, and requiring very cautious treatment. Others as stoutly assert that plica is merely the product of neglect and dirt, and that it requires for cure nothing but the shears and cleanliness. This difference of opinion is not alone between foreign observers and the physicians of Poland, but the latter themselves are divided on the question. Among those who hold the first opinion are Lafontaine, who asserts that he saw the disease in a new-born infant, and Robin, surgeon to Frederick the Great, who relates the following experiment. He shaved the heads of two boys on whom the disease was just beginning to appear, and then paid particular attention to the hair during its growth. His attention was in vain, for the disease re-appeared. Schlegel agrees with Lafontaine and Robin; and more lately among foreign physicians, Chaumeton and Mouton, who were attached to the French army when in Poland during the late war, hold the same opinion. It is further argued in support of their view, that if plica owed its origin merely to want of cleanliness, it would not be confined to Poland, but should be equally found among the Russian, Prussian, and Spanish peasants, who are as dirty in their habits as the lower classes of Poland; that its appearance frequently constitutes the marked crisis of some other disease; that it is accompanied with a peculiar secretion; that the nails, which are known to be merely a variety of the same tissue as the hair, are in bad cases engaged by a similar diseased action; and that the bulbs of the hair exude a peculiar viscid secretion, and are found swollen and acutely sensible. In conclusion, it is asserted that plica cannot be suddenly removed without great danger to the patient. On the other hand, Davidson, a Scotchman, who was physician to one of the kings of Poland, published a work in 1668, in which he pithily observes of the disease, "Nullus habet, nisi qui non velit carere," and declares that he treated and cured more than 10,000 cases; that he always, without hesitation, cut off the plicæ, and that no injurious consequences supervened. Larrey, Chamsern, Gase, Kerckhoff, &c., who had opportunities during the late war of investigating the disease in Poland, support the opinion promulgated so many years since by Davidson, and assert with him that the fear entertained of cutting off plica is a mere chimera. In support of their opinions they point to the facts, that Polish recruits are always cured by their hair being cut and their habits changed after their entrance into the army; that the disease is almost invariably confined to the lowest classes, and principally to the Jews, who form an immense proportion of the population of Poland, and are universally acknowledged to be the filthiest people on the face of the earth. They further state that strangers residing in Poland never contract the disease unless they sink so low as to approximate to the natives in manners and dirt, and that the disease is disappearing just in proportion as improved habits and comforts are extending; moreover, that in cutting off a plica, as in the case related by Kerckhoff, and which we have already noticed, the agglutinated hair is found distinct and round at the roots. To the last argument it is replied, and with justice, that the diseased action which produced the plica having ceased, the hair which has continued to grow will after a little time have pushed out from the scalp the agglutinated mass of hair, and hence that the soundness of the hair at the roots is no proof that diseased action had not previously existed. Larrey is further of opinion that the urgent symptoms, as pains in the bones, joints, &c., which occasionally precede or accompany plica, owe their origin to a complication of syphilis. Jourdan, the translator of Schlegel and Lafon-

* Observations Médicales par Jos. Rom. Louis Kerckhoff, Doctor en Médecine—Médecin de l'Armée des Pays Bas, &c. Published in vol. vi. of Medical Transactions of College of Physicians in London.

taine's works, and the writer of the article "Plique" in the Dictionnaire des Sciences Médicales, suggests that there should be a distinction made of plica into true and false; true plica being that form of the disease described by Schlegel, in which the bulbs of the hair are inflamed, become enlarged and acutely sensible, produce a rapid growth of hair, and at the same time glue it together by a peculiar secretion which is poured out from the skin and the hairy bulbs, and even forces its way through the substance of the hair near the skin. False plica Jourdan considers as a mere accidental matting of the hair, dependent altogether on external causes. This view would probably reconcile many of the conflicting statements, but even in our investigation of the nature of what, according to this classification, we may call true plica, we meet with great difficulties. We have not information before us sufficiently accurate to enable us to say what is the precise source of the fetid secretion which glues the hairs together, —whether it is poured out by the bulbs of the hair, the sebaceous follicles, or the general surface of the skin. The surface of the skin where the hair is affected is described as being in a state of ulceration in some cases, but this may be an effect of the state of the hair rather than a cause of it; and finally, the state of the scalp may, for aught that we yet know, arise from the presence of some ordinary eruption, the matting of the hair and the viscid fetid secretion being complications added by the influence of extraneous circumstances. Lafontaine asserts that hair presenting shades of red is more liable to plica than hair of other colours, but Schlegel states that he never observed any difference of liability arising from colour.

Alibert makes three subdivisions of plica, according to the form it may chance to assume. He calls his first species "plique multiforme," where the hairs form a great number of ropes, hanging round the patient's face like serpents round the Gorgon's head; his second species, "plique à queue, ou solitaire," in which the whole hair is united into one long plica or tail, principally met with among females, and on those wearing their hair after the national Polish fashion. He calls his third species "plique en masse, ou larvée," in which the hair is all melted into one cake, covering the head like a helmet. These subdivisions are, however, useless; for the varied forms which the hair assumes, appear to be merely the result of external accidental circumstance.

The people of Poland believe that plica is contagious, but there does not appear to be satisfactory ground for this belief. Kerckhoff inoculated children and himself with the viscid secretion, and failed to propagate the disease; and Davidson, who had ample experience, is also a disbeliever in its contagion. Alibert, on Robin's authority, states that a Polish nobleman who kept a seraglio, of which four of the inmates had plica, never contracted the disease. On the other side, Lafontaine and some of the French observers of plica believe that it is a contagious disease.

Symptoms.—The premonitory symptoms of an attack of plica, according to those who look upon it as a peculiar disease, are pains in the back and limbs, vertigo, lachrymation, with violent itching sensation of pricking, and increased sensibility of the hairy scalp, followed by a copious secretion of a peculiar viscid sweat, of the consistence of honey, which speedily glues the hairs together. On the appearance of this secretion, the previous symptoms disappear. It is said in Poland that one of the most usual forerunners of an attack of the disease is a perverted appetite, and hence there is a saying, "Sæpe sub plica, latet seu fœtus seu plica." Of all the symptoms, however, none give a certainty of the approach of the disease except the breaking out of the viscid sweat. Cases are given by Alibert, Lafontaine, Schlegel, &c., of plica appearing as a crisis of, or alternating with internal diseases; according to their accounts, the internal affection was alleviated when the plica secretion was abundant, and *vice versâ*. When the hair is cut very close, in what we may call true plica, a brownish fluid frequently exudes from the bulbs of the hair, and the appearance of this fluid has given rise to the belief that the hair poured out blood.

Treatment.—The directions for treatment, of course, vary as much as the opinions on the nature of the disease; those who look upon the disease as the product of dirt, directing us to cut off at once without dread the matted mass, and afterwards trust for a cure to soap and combing; and on the other hand, those who see in the cutaneous affection the elimination from the system of a poison, which they call "virus trichomaticus," warn us in the strongest language not to meddle, lest we turn the poison back on the brain or lungs, &c. Lafontaine extends the supposition of the existence of a peculiar virus so far as to direct us, when any symptoms appear which we suspect are premonitory of the approach of plica, to hasten its appearance by warm cataplasms, sinapisms, &c. to the scalp. Under whatever view we regard the disease, the supposition of the existence of a virus is a mere assumption, and the advice to force the eruption is only an illustration of the prevalence of the same bad principle which of old so erroneously directed us to force out the virus of other eruptive diseases, as small-pox or measles. Mouton, to whose opinions we have already alluded, says we may without fear cut off plica if it be dry, and if it be united to the scalp by hair sound near the roots, which he says indicates that the diseased action which had produced the plica had ceased; but that we ought not to interfere as long as the bulbs of the hair are inflamed and sensible, and continue to pour out a viscid secretion, keeping the hair matted at its roots. Various remedies are recommended in Poland. Lycopodium is much used by the people, who use it both as an external application and an internal medicine; but there does not seem to be any settled rule or principle of treatment. Preparations of mercury, antimony, sulphur, zinc, baths, emetics, diaphoretics, and narcotics, have all in turn been recommended. Among these, the golden sulphuret of antimony is probably the remedy on which most reliance is placed. Patients who are debilitated or advanced in life require, it is said, the administration of tonics; and it is scarcely requisite to observe that an occasional application of strong mercurial ointment to the hair is requisite to destroy the vermin,

which breed in it with immense rapidity. It is unnecessary to say any thing on the management of false plica, in which the matting of the hair, arising from neglect, is present without any disease of the bulbs.

D. J. Corrigan.

PNEUMONIA, (πνευμονία); *peripneumonia*, or *peripneumony*, (περιπνευμονία); *pneumonitis, pulmonitis, peripneumonia vera*, (from πνεύμων, -ονος, *pulmo, a lung*, or *the lungs*;) are names given to an inflammation of the parenchyma of the lung, which is the most common of all the dangerous inflammations.

Peripneumony and pneumonia are the names applied by Hippocrates, Aretæus, Celsus, and other ancient writers on medicine, to most of the acute diseases of the chest without severe pain; those connected with this symptom being termed pleurisies. Many succeeding authors have not admitted this distinction; and inflammations of the lung have been as often described under the name of pleurisy as under that of pneumonia. The earlier cultivators of morbid anatomy, Valsalva and Morgagni, were the first to prove the distinct existence of the two diseases, but they gave no means of distinguishing them before death. Hence Cullen, although he makes pleurisy a species of the genus pneumonia, expresses his belief that the term pleurisy might with propriety be applied to every case of the disease. It is only through the aid of auscultation that pneumonia and pleurisy have been recognised as distinct diseases, and it is therefore only in the writings of those who have employed this method of diagnosis that the truly distinctive characters of pneumonia can be found.

Cullen's generic definition of pneumonia more frequently holds good than his specific distinctions, on the correctness of which, as we have just remarked, he does not insist. *Fever, pain in some part of the chest, difficult breathing, and cough*, which he ascribes to the genus pneumonia, are, in the greater number of instances, present in both pleural and pulmonary inflammation; but there are cases of both kinds in which each of these symptoms is absent. The specific definitions of pleurisy and pneumonia are still more frequently at fault; thus the *softer pulse, duller pain, constant dyspnœa, and livid face*, are as much the characters of severe bronchitis as of pneumonia, to which he ascribes them; and the *hard pulse, acute pain, increased on inspiration, painful decubitus on the affected side, painful cough, first dry, and afterwards with expectoration, often bloody*, the assigned characters of pleurisy, indicate pleuro-pneumonia as much as pleurisy, and are sometimes presented by bronchitis or peripneumony joined with pleurodyne.

The following is the character which we would give as most generally applicable to pneumonia:—*Fever, with more or less pain in some part of the chest; accelerated and sometimes oppressed breathing; cough, with viscid and rusty-coloured expectoration; at first the crepitant rhonchus, afterwards bronchial respiration, and bronchophony, with dulness of sound on percussion in some part of the thorax.* In this, however, as in many other diseases, pathology is the only sure basis of definition: pathologically, therefore, pneumonia consists essentially of an inflammation of the parenchyma of the lungs, occasionally but not necessarily extending to the pleura investing them; which inflammation, although it usually occasions a certain combination of general symptoms, is not so essentially connected with these symptoms as to receive from them an infallibly pathognomonic character.

The pathological and anatomical characters of pneumonia, as well as its relation to general symptoms, have been industriously and successfully investigated by the French pathologists, particularly by Laennec and Andral; and it is to them we owe the most important matter of the following history. Andral calls the disease pleuro-pneumonia, from the circumstance of some part of the pleural covering of the lung being involved in the inflammation: we do not deem it necessary to deviate from the example of Laennec, who confines this term to that form of the disease in which the pleura is affected in a sufficient degree to modify the pulmonary inflammation. This will be noticed among the complications of the disease.

I. General History of Pneumonia.

Symptoms.—Like other severe inflammations, pneumonia is accompanied by a pyrexia, which often commences in a rigor, prior to any other symptom. Sometimes this shivering fit does not occur until after the establishment of pain, dyspnœa, and other symptoms; and in some cases, especially where the pneumonia succeeds to a bronchitis, or when the first attack is felt in bed, it is not observed at all. Frequently, a feeling of great depression and languor, with pains in the back and limbs, and a disordered state of the stomach and bowels, precede the attack; then a shivering fit comes on, followed by a violent reaction, with great heat of the skin, and during this hot stage the local symptoms of heat, pain and oppression in the chest, with more or less cough, are developed. The pyrexia is generally very intense, and in plethoric individuals is accompanied by great flushing of the cheeks, injection of the conjunctivæ, headache, and other signs of local determination of blood. This general fever may precede by a day or two the local symptoms, sometimes diminishing in intensity when they appear; and sometimes continuing and masking them. The pain in the chest, which when present is generally an early symptom, varies greatly in degree, being sometimes very intense, sometimes diffused and dull; frequently it is a deep-seated feeling of heat and weight rather than of pain. Most commonly it is deep-seated in the anterior parts of the chest, below the sternum or below the mamma, sometimes under the scapula; acute pains are more common in either of the sides. Andral says that there is never any pain without an extension of the inflammation to the pleura; (Clinique Médicale, tom. ii. p. 327;) Laennec asserts, on the contrary, that there is frequently pain, and sometimes a point of sharp pain when no pleurisy is present, (De l'Auscultation Méd. tom. i. p. 432;) this is more in accordance with our own observation, and it is remarkable that in several of the cases described by Andral, where there were various degrees of pain, no mention is made of any inflammatory appearances on the pleura on ex-

amination after death. (Op. cit. obs. 29, 38, 43, 46.) There is commonly a cough at this time, which aggravates the accompanying pain, or causes a feeling of pain when none is otherwise present. It is generally at first either dry or accompanied with simple catarrhal expectoration, and short, not occurring in paroxysms, and is by no means proportionate to the intensity of the inflammation; it is sometimes so slight as scarcely to be noticed by either patient or attendants. The shortness of breathing or dyspnœa, which is commonly an early symptom, is a better measure of the extent and severity of the disease; but we should be mistaken if we always trusted to the feelings of our patients as to its presence or degree. In its slighter degrees they are not sensible of it, a supplementary quickness of breathing removing the sensation of dyspnœa; but an attentive observer readily discovers this quicker and shorter respiration, and the more perceptible elevation of the ribs and depression of the diaphragm that attend it. The number of respirations in a minute, which is in health about twenty in the adult, may now be counted at thirty and upwards, and in severe cases it occasionally exceeds sixty. In some examples, especially where the attack has been sudden, the dyspnœa is greater and more obvious, causing the patient to assume one particular posture, on his side, or on his back with his shoulders elevated; and from their sensibly increasing his oppression, he avoids all exertions of movement and speech; this difficulty of breathing continues to increase as the disease advances. The pulse is quick, and in most instances sharp. With respect to its hardness, it is subject to great diversity, but in many cases it is (notwithstanding Cullen's definition) both hard and full at the commencement of the disease. This character, however, rarely continues long, and often the pulse is weak and small from the beginning. Under the febrile excitement the urine is more highly coloured than in most other symptomatic fevers; and there is more or less of the thirst, white or brown fur on the tongue, loss of appetite, pain in the head and limbs, depression of the strength, &c., than usually characterize them, and blood drawn generally exhibits a buffed and concave crassamentum. This fever may affect particular organs especially, with the production of other symptoms; as the brain with delirium, the stomach with sickness, &c.; but these complications will be better considered hereafter.

The symptoms usually continue in this state from twenty-four to forty-eight hours. At a period varying within that space, the cough, which was hitherto dry or with the expectoration of common bronchitis, becomes accompanied by the expectoration of a very characteristic kind of sputa. They are of a yellow-reddish or rusty tinge of various shades, semi-transparent, tenacious, and running together into one mass. At first this expectoration scarcely exceeds the tenacity of the white of an egg, resembling in all but its colour the sputa of acute bronchitis, and, when poured out, falls in glutinous strings; but it often becomes so viscid that inverting the vessel and even shaking it in that position will not detach it. The same tenacity sometimes imprisons in the mass a multitude of little air bubbles, which may produce a spumous appearance. The colour may vary in numberless gradations from a light reddish or greenish yellow to a deep orange red or rusty hue. All these tints proceed from various proportions of blood intimately combined with the secretion of the bronchial membrane. This new feature added to the other symptoms is quite characteristic of the disease. The dyspnœa is frequently increased at this period, the inspirations being obviously short and quick; and if the disease is extensive, oppression becomes very urgent. The pain, on the other hand, is commonly diminished; sometimes it remains and prevents the patient from lying on the affected side. The most common posture is therefore on the back, as lying on the same side would restrain the supplementary expansion which is required there. Often connected with this posture, one of the cheeks is flushed, but there is no constant correspondence, as Dr. Stack has observed, between this and the side affected.

The disease may go on in favourable cases to the third or fourth day, and then decline in consequence of the resolution of the inflammation, which is indicated by a general alleviation of the symptoms. The pain and dyspnœa are considerably relieved; the cough becomes looser and less distressing; the expectoration less viscid and rusty-coloured, more abundant, and resembling the sputa of bronchitis. The pulse loses its sharpness, and more gradually its frequency; the skin becomes cooler, and sometimes moistened with perspiration; the urine is increased in quantity, and deposits a sediment. Sometimes this amelioration is a speedy process, and restores the patient to a state of convalescence in six or eight days; but it is sometimes more protracted, slight exacerbations recurring every evening, and some of the symptoms remaining stationary, and extending the duration of the disease to a fortnight or three weeks. The quickness of the pulse, and dyspnœa, sometimes with cough, are the symptoms most apt to linger, with a temporary recurrence of the sanguinolent tinge of the sputa; and although there is a great improvement in other respects, they are to be regarded as signs of a lurking disease which a slight cause may be sufficient to aggravate into a severe relapse.

The increase of the disease in more formidable cases manifests itself on the third or fourth day by an augmentation of the dyspnœa, which becomes so urgent as to oblige the patient to have his head and shoulders raised; and the inspirations short, forced, and amounting to from forty to sixty in a minute, are effected by sudden elevations of the ribs and depressions of the diaphragm; in some cases the side not affected obviously partaking disproportionately in the respiratory effort. The cough is sometimes more frequent, but this is not constantly present in aggravated cases. The viscidity and colour of the expectoration more exactly correspond with the increase of the disease; the tenacity reaches its acmé, so as to adhere strongly when the vessel is inverted, and even shaken in that position; and the colour is more deeply tinged with blood. The pulse becomes quicker, and often weaker and smaller. There is great depression of the bodily powers; and the patient's attention is engrossed by efforts to breathe under

the weight and oppression which he feels at the chest. The tongue is often loaded and dry: the skin sometimes continues harsh and hot; in other instances there are partial perspirations and coldness of the surface. Occasionally the features are livid; but this is less common in pneumonia than in severe bronchitis. Sometimes there is delirium or coma; these are dangerous symptoms, especially in old persons; and when present, they frequently disguise the character of the disease. We have known a case of delirium occurring in a supposed idiopathic fever, and another of delirium tremens, which proved fatal through an inflammation of the lung, which was only discovered after death. Hippocrates noticed the danger implied by this symptom; and succeeding authors have confirmed his remark. Laennec describes comatose affections, the result of sanguineous congestions in the head, as of much more unfavourable import than fierce delirium.

When the disease terminates favourably, the amendment is generally marked by some critical evacuation, such as perspiration, diarrhœa, expectoration, or a lateritious deposit in the urine. Of these Laennec considered the last to be the most common: Frank and Andral describe perspiration as more frequent; from our own observation we should say that these two are commonly conjoined; and there seldom occurs in pneumonia a perspiration that can be called critical, without at the same time a deposit in the urine. The latter, however, sometimes takes place when there is no manifest increase of the cutaneous perspiration. A copious expectoration does not occur so frequently as it is described by Sydenham and Cullen to have done; and it is probable that the character of the disease has in some measure changed since their time; for, as Laennec remarks, there are some epidemic forms of pneumonia which very commonly terminate by free expectoration, and which generally go on favourably after this is once established. Other critical phenomena happen more rarely; as epistaxis, hematuria or some other hemorrhage, the menstrual discharge, &c. The commencement of the amendment is generally pretty obvious, and usually occurs in the morning. The observations of Andral have in some measure confirmed the opinions of Hippocrates and other authors, ancient and modern, that there are certain days in the duration of the disease in which there is a greater tendency to amelioration. Of ninety-three cases, he found twenty-three give way on the seventh, thirteen on the eleventh, eleven on the fourteenth, and nine on the twentieth days. The recoveries in the remaining cases commenced on twelve out of forty-two non-critical days, as many as eleven being ascribed to the tenth day. (Clin. Méd. t. ii. p. 365.) Thus the recoveries on critical days averaged as high as fourteen, while those on non-critical scarcely exceeded three.

In cases of favourable issue, after continuing with greater or less intensity for the various periods just mentioned, and generally on the occurrence of some of the critical phenomena before named, the symptoms become mitigated, and a notable amendment takes place. The dyspnœa becomes less oppressive; the cough less constant; the expectoration less viscid and sanguinolent, and more free; and the pulse less frequent, often with an increase of fulness. The fever generally diminishes with the inflammation; if a critical perspiration have not already appeared, the skin soon becomes soft and moist; the tongue gets cleaner, and the thirst abates. Generally the patient is fully sensible of his real improvement; he feels each day a great accession of strength, and advances rapidly to convalescence. Some dyspnœa and quickness of pulse generally linger after the other symptoms; and there is sometimes a cough with an expectoration of bronchitic mucus, which in some cases remains for some time, but more commonly is carried off with those changes in the sputa which are observed in acute bronchitis. The breathing and pulse in some instances do not assume their natural slowness until after the patient has entered on a tonic and restorative method of treatment.

Relapses are by no means uncommon in recovery from pneumonia; and they are marked by a recurrence of the characteristic symptoms,—pain, shortness of breath, cough, and viscid sanguinolent expectoration. The fever has seldom so sthenic a character as at the first attack, and frequently it is decidedly adynamic, the strength having been reduced by the previous disease and treatment. Hence a relapse, if a serious one, is often more dangerous than the first attack.

The progress of fatal cases of pneumonia is marked by a continued aggravation of the dyspnœa, with increasing failure of the strength. The cough becomes less capable of expectorating the sputa, which sometimes retain their viscidity and sanguinolent hue as long as any are voided. In the greater number of instances there is a total suppression of the expectoration for some hours before death; but in others it is still excreted, but of a different character. Sometimes it is merely pituitous, transparent, or of a dirty tinge; sometimes it is a semi-opaque dirty mucus; occasionally purulent specks of a yellowish white colour are visible in it; more rarely it is purulent, with streaks of blood, or in opaque nummulary forms of a yellowish white colour, consisting of pus and a little mucus. Not unfrequently various mixtures of these different kinds are seen together; but the whole sputa in the latter stages of the disease are generally scanty. Andral describes sputa of a very remarkable kind as occasionally occurring in the last stage of pneumonia: they consist of a slightly glutinous liquid of a reddish brown colour, resembling liquorice-water or thin syrup of prunes. Rarely, sputa of a mixed greenish and dirty red or grey colour, and putrid fetor, are the last observed. With any of these changes in the expectoration the state of the patient puts on a worse aspect; the pulse becomes thready and intermittent; the countenance pallid, cadaverous, and bedewed with a cold sweat; the lips livid, the breathing gasping and convulsive, with a rattle in the throat; the sensorial functions, if entire before, now give way, and the patient dies asphyxiated.

Such is the general type of pneumonia as it presents itself to the semeiological observer. This appears to be the proper place to enumerate historically the causes which have been observed to excite the disease, or favour its production; and we shall afterwards proceed to scrutinize more

closely the various changes which constitute its pathological history. Unfortunately the principal part of our knowledge of these changes has been derived from a study of their effects in the dead body. It will, therefore, give better ground to our pathology, if, after enumerating the causes, we describe the anatomical characters of pneumonia.

[Pneumonia and acute rheumatism are diseases in which the increase in the proportion of the fibrin of the blood has been the greatest. In 84 bleedings, practised by M. Andral, (*Hématologie Pathologique*, p. 87: Paris, 1843, or Amer. edit. 1844,) on the course of well-marked pneumonia, there were only seven in which the proportion oscillated between four and five in the 1000; in the 77 others, it exceeded this;—maintaining itself, in eleven cases, between five and six; in nineteen between six and seven; in fifteen between seven and eight; in seventeen between eight and nine; in nine between nine and ten; and in six it rose as high as ten, and even exceeded this a little.]

Causes.—The previous occurrence of the disease seems more than any other circumstance to predispose to pneumonia. Rush describes the case of a German living in Philadelphia, who had the disease twenty-eight times. Andral gives a case in which it recurred the sixteenth time within eleven years. (Clin. Méd. t. ii. p. 192.) Dezoteux treated seven times a pneumonia in a subject who had suffered from it fifteen times, (Dict. des Sciences Méd. t. xliii. p. 396); and Chomel alludes to its recurrence the tenth time in the same individual. (Dict. de Méd. Art. *Pneumonie*.) Perhaps the only other circumstance that can be fairly viewed as a predisposing cause, is the presence of tubercles in the lungs. It has been said that the adult age, the male sex, a sanguine temperament, and certain occupations, as those of singers, street-criers, public speakers, &c. predispose to the disease; but if it occurs more frequently in persons under such circumstances, this is to be referred to their being more exposed to the existing causes, rather than to any constitutional predisposition. [M. Grisolle, (*Traité Pratique de la Pneumonie*, &c. Paris, 1841,) has, indeed, found that when males and females are equally exposed to field and other open air labour, the proportion attacked with the disease is the same. In infancy, too, females suffer as much as males.] With regard to age, it has not been found, since the disease has been accurately distinguished, that any age is particularly exempt from it. The symptoms are generally more prominent in middle life, and it is therefore more readily distinguished; but infancy and old age appear to be equally liable to it. M. Guersent reports the disease to be very common and fatal among children; and that of the deaths among those in the hospital of sick children in Paris, before the completion of the first dentition, three-fifths occur from pneumonia, chiefly latent. (Ibid. t. viii. p. 96.) From our own observation we are inclined to consider young children as more frequently the subjects of pneumonia than adults. Of fifty-five cases attended by Mr. Byam and the writer during one year, at a dispensary in the parish of St. Marylebone, thirty-two were of the age of six years or under. Neither Laennec nor Chomel concurs with Stoll and Auenbrugger in considering persons of sedentary modes of life, such as tailors, the most liable to pneumonia. Masons, porters, out-door labourers, and carpenters, present the greatest number of examples, which is plainly to be ascribed to their being more exposed to the exciting causes. The same circumstance is, as M. Chomel observes, the reason why men suffer more frequently than women. Out of ninety-seven cases which occurred in the wards of La Charité, under his care, seventy-three were men, although the number of patients of either sex was nearly the same. (Dict. de Méd. t. xvii. p. 211.)

Cold, excessive exertion of the lungs by violent exercise or by the voice, the inhalation of irritating vapours and asphyxiating gases, wounds of the lungs and blows on the chest, the bite of the rattlesnake, and the action of some other poisons, as fungi, may be named as exciting causes of pneumonia. To these may be added several diseases on which this inflammation occasionally becomes engrafted; such as bronchitis, hooping-cough, pulmonary apoplexy, phthisis, the exanthematous, continued, and sometimes traumatic fevers, particularly those supervening on extensive injuries or operations. It is so frequently complicated with hooping-cough, small-pox, and measles in children, that we consider the danger of these affections in a great measure to arise from this complication. In common with other inflammations, it may be occasioned by the suppression of habitual discharges, as the catamenia, hemorrhoids, and other hemorrhages, and issues or ulcers of long standing. The inflammations of gout, rheumatism, and cutaneous diseases, are sometimes transferred to the lungs by metastasis.

The influence of cold in producing inflammation of the lungs is sufficiently apparent in the much greater prevalence of the disease in cold seasons and cold climates. Of ninety-seven cases recorded by Louis in Chomel's wards at La Charité during five years, eighty-one occurred between February and August, and only sixteen in the remaining five months of these years. Of the cases described by Andral, the number occurring in March and April amounted to a third of the whole; the fewest took place in May, October, and November, and the remaining months had an equal share. Of two hundred and forty-three cases which were treated at the Edinburgh New Town Dispensary during three years, ending September 1, 1824, sixty-seven occurred from 1st September to 1st December; one hundred and four from 1st December to 1st March; ninety-four from 1st March to 1st June; and sixty-eight from 1st June to 1st September. We have observed in London nearly an equal prevalence of the disease from the beginning of December to the end of April, and a considerably smaller proportion in the remaining months; but it appears generally that the latter winter and early spring months are most fertile in producing pneumonia in these climates.

[Recent statistical observations show, that three times as many cases of pneumonia have been observed in the French hospitals in the first six months of the year as in the last, and such was nearly the proportion in the Pennsylvania Hospital during the years 1840, 1841 and 1842,—39

cases having been received in the first six months, 12 in the last.]

Pinel and Briehetau consider the most frequent cause of pneumonia to be the sudden exposure of the heated body to cold after violent exertion, especially that of the voice. (Dict. des Sc. Méd. t. xliii. p. 396.) Laennec remarks on this point that cold long-continued, or applied when the body is only moderately heated and covered with perspiration, is much more powerful as a cause of pneumonia, than when cold succeeds to an excessive heat, and is not long continued: "the Russian who rolls himself in the snow after coming out of a hot bath, or the baker who goes from his heated oven, almost naked, into an atmosphere of a temperature below the freezing point, is not liable to attacks of the disease; while the porters, whose occupation leads them to stand for a length of time at the corners of the streets, are frequently affected by it." (Dr. Forbes's Transl. 3d edit. p. 225.) It is certain that cold winds or cooling influences long applied, are more sure to produce the disease than mere changes of temperature; and the perspiring body must obviously suffer more as it is exposed to the additional cooling agency of evaporation. Transitions of temperature of short duration are more effectually resisted by the body; and if the reaction from them produce any inflammation, it is generally one of the mucous membrane, a coryza, a cynanche, or a bronchitis: it is when the cold has penetrated deeply that the parenchymatous inflammations more frequently follow. Hence, besides cold winds, any kind of exposure at a low temperature, as on horseback, sleeping in the open air, &c., occasionally excite pneumonia. Rarely it has been produced by drinking cold liquids when the body is in profuse perspiration, and sometimes by intemperate indulgence in alcoholic liquors.

The cause of the greater number of cases is, however, either unknown, or of the obscure character in which epidemic and endemic influences are involved. Of seventy-nine cases investigated by Chomel, fourteen of the individuals had been exposed to cold; five had taken an excess of wine, one had been over-fatigued, one had suffered great mental excitement, one had breathed for some length of time the fumes of charcoal, and the remaining fifty-six could assign no cause for their complaint. (Dict. de Méd. t. xvii. p. 213.) The epidemic occurrence of the disease is clearly proved; and such has been its extent, that a contagious nature has been ascribed to it. Laennec remarks that epidemic pneumonia is probably often owing to deleterious miasms, suspended in the air, entering the circulation and operating particularly on the lungs, as the poison of the rattlesnake and of some fungi is said to do: hence many persons are seized in their very chambers in spite of the utmost care taken of their health. (Op. cit. p. 225.) In many epidemics it is difficult to decide the amount of influence which known physical causes, such as changes of temperature and moisture, may have in determining the production of morbific effects on the body; but no meteorological observations have ever discovered in the physical conditions of the air a sufficient cause for the remarkable prevalence of this disease, which occasionally constitutes a third, or even a half of the acute complaints of our hospitals. In one of these epidemics, it was observed by Huxham that the disease showed itself in the form of bronchitis in low and damp situations, while at a short distance, on elevated spots, it prevailed as a peripneumony. Elevated districts are perhaps the more liable to pneumonia because they are more exposed and colder; whereas the humid air of low valleys, whilst it diminishes the intensity of the cold, relaxes more the mucous surfaces, and renders them the weaker points of the circulation. The account of Hippocrates would not seem to coincide with this statement, as he describes pneumonia as common in marshy districts, (De Aere, &c.,) but that he probably includes severe bronchitis also under this name. Hoffmann ascribes to pneumonia an endemic character in some parts of Westphalia, Sweden, Pomerania, Denmark, and Russia; but the physical climates of these countries is a sufficient explanation of its prevalence, and Britain may as fairly be added to the list. Nor are the milder climates free: at Nice, Genoa, Pisa and Florence, the disease prevails greatly, and cuts off a good many of the inhabitants. (Clark on the Influence of Climate, 2d edit. p. 121.) The neighbourhood of Mount Vesuvius is remarkable for the frequency of its occurrence: here it may more properly be called endemic, as it may reasonably be attributed to the noxious exhalations which prevail there. (Vivenzi Epist. ad Haller. iv. Bouillet, Mém. sur les Pleuro-pneumonies Epidem.)

[In the United States, it is a very common disease, and in some parts of it more common than in others.]

II. Anatomical Characters of Acute Pneumonia.

We owe the most accurate information which we possess on the morbid anatomy of this disease to the researches of the French pathologists, particularly those of Laennec and Andral. There are, however, many doubtful points relating to the essential seat and effects of the inflammation which still remain to be cleared up before our pathology of pneumonia can be considered accurate.

Laennec arranges the general effects of inflammation on the lungs into three stages or degrees, each of which is distinguished by marked characters: The first degree, or *engorgement;* the second degree, or *hepatization;* the third degree, or *purulent* infiltration. These are the common effects which inflammation in its general course produces in the lung. Abscess and gangrene are of uncommon occurrence, and to be viewed as exceptions, rather than as regular events.

In the first degree of inflammation, the engorged or obstructed state, the lung is externally of a dark or livid red colour, to which a slight, whitish opacity of the pleura sometimes gives a violet hue; it is heavier and more substantial to the touch than a healthy lung: when pressed, it yields less of the crepitating sound and feel, and instead of generally collapsing under the pressure, and partially rising on its removal, it receives and retains the impression of each finger, giving the feeling of a liquid contained in cellular substance, as in an œdematous limb. On examining it closely through the transparent pleura, there are seen numerous little round bubbles of air without

the angularity of the natural vesicular structure; and the septa, which are commonly very visible, are scarcely to be discerned. On cutting into the lung in this state, a bloody serum, containing numerous minute air-bubbles, flows from it; sometimes in great abundance and almost clear, sometimes more scanty and sanguinolent, or turbid, and with various proportions of the spumous bubbles. The substance thus cut into is of a red colour, of various shades; crimson, dark red, brown red, chocolate red, or of a livid puce colour, approaching to black. The vesicular texture of the lung can still be discerned, particularly after the serum has drained from it; and by pressing it gently and washing it repeatedly, the natural colour, appearance, and elasticity may in some degree be restored. There are varieties in this state of engorgement, some of which depend on the degree or duration of the inflammation, and others on individual peculiarity. The progress which the inflammation has made is pretty accurately represented by the defect of air in the tissue; in the slightest degree, there being a good deal of air, the lung feels still crepitous, and the serum which flows from it is very frothy. The quantity of serum indicates rather the intensity of the inflammation than its duration; but, as far as we have observed, it partly also depends on the coagulability of the blood. In recent severe inflammations, which have proved fatal in the first stage, it is generally very copious; but in those which have endured for several days, it is seldom as abundant even in points where the second stage has not commenced. The progress towards this second stage is marked by a paler colour, a diminished quantity of both liquid and air, and an increasing solidity of the tissue. There is another variety of the inflammatory engorgement, probably depending more on the state of the blood than on the degree of inflammation: the lung presents an extreme lividity, and when cut, instead of yielding serum, exudes slowly a dark, grumous blood in greater or less quantity. This appearance is noticed by Chomel, (Dict. de Méd. t. xvii. p. 235,) as occurring particularly in cases of pneumonia complicated with other acute affections, as fevers; and we have repeatedly observed it. The writer, together with Mr. Byam, recently examined the lungs of a child of eighteen months, affected with chronic hydrocephalus, who was carried off by an attack of pneumonia: both lungs were partly hepatized, and partly of a very dark red colour, appearing of a livid purple through the pleura; some parts of this inflammatory engorgement still contained a good deal of air, and, when pressed, exuded merely a little grumous blood, mixed with bubbles. Other parts of the lung were hepatized. The child had repeated attacks of convulsions during the two days before his death, and between four and five ounces of serum were found between the membranes and in the ventricles of the brain, which was uncommonly voluminous. But what we think most worthy of remark is, that the blood was fluid in all the vessels examined, and this we apprehend to be the cause of the peculiar character of this inflammatory engorgement of the lung. This was probably the case, also, in the complications noticed by M. Chomel, for a fluid state of the blood is very commonly observed in typhoid fevers after death. We consider that these circumstances render it probable that the separation of the serum in the engorged lung is more a cadaveric than a pathological process; and that, as the blood coagulates in the distended vessels, its serum transudes into the vesicular structure. Where, on the other hand, the blood does not coagulate, it is too thick a fluid to exude into the cells, or to flow freely as serum does when the lung is cut. We do not maintain that there is no interstitial serous effusion during life; the analogy of other inflamed parts renders it probable that it does take place, but, we suspect, by no means to the extent which is commonly found in the engorged lung after death. We shall revert to this point when speaking of the pathology.

The colour of the lung inflamed to the first degree depends on the blood in it, in some cases deepened or modified by the black pulmonary matter: in the lungs of old people the abundance of this matter gives the inflammatory infarctus a blacker or more dingy hue; whilst in children the colour of the blood entirely prevails. Although very much heavier than was natural, a portion of lung in this state retains enough air to prevent it from sinking in water. Another remarkable change wrought in the lung by the most considerable degrees of inflammatory engorgement, is a diminution in its molecular cohesion, so that the fingers break through or tear its substance much more readily than in a healthy lung. This effect was first described by Andral, (Clinique Médicale, t. ii. p. 307,) and afterwards by Chomel, (Dict. de Méd. loc. cit.) Andral formerly considered this softening of the tissue a test by which inflammatory engorgement might be distinguished from that produced by gravitation, the mechanical hyperæmia; but he has since abandoned this opinion, and, as did Laennec in his clinical lectures, referred the more easily lacerable state of the lung to the physical effect of an unusual proportion of blood in it. "The reason of this fact will be readily understood if we reflect that when the lung contains a much larger proportion of air than of blood, the parietes of the bronchia, when pressed by the finger, press in their turn on the compressible fluid they contain, and in this way, by compressing or expelling the air, retire before the pressure of the finger, and so escape being ruptured. But when the lung contains a larger proportion of blood than of air, the former fluid being almost wholly incompressible, the pulmonary tissue cannot recede from under the finger, and is therefore easily ruptured." (Andral's Pathological Anatomy, *translation*, vol. ii. p. 510.) Chomel, however, in his article before quoted, published in 1827, still maintains the applicability of this test; he says that the merely congested lung preserves its natural consistence; but the inflamed lung in great measure loses it, insomuch that it requires very little force to make the fingers break through its substance. Our own examinations have led to conclusions somewhat different from those of both these authors. We are convinced that both inflammatory and mechanical engorgements tend to diminish the cohesion of the parenchyma more than the mere increase of liquid in it can explain, and for the

following reasons: 1. if a portion of the healthy tissue adjoining an engorged portion be pulled gently, a laceration takes place in the latter before the healthy portion is stretched to the utmost, and with a much smaller degree of force than is required to tear this healthy portion: 2. the fragility of the tissue is not always in proportion to the quantity of liquid in it: 3. an engorged portion of lung does not lose its greater friability when the blood has been gently pressed and washed out of it. We have never been able to discover any physical difference between the first stage of marked inflammation and that engorgement supposed to be a mechanical congestion in the most dependent part of the lung occurring shortly before and after death; and it would appear from the observations of Laennec, that the resemblance between the latter state and pneumonia is not confined to the anatomical appearances; for where the agony, or moribund state is prolonged, points of hepatization are formed in the most congested portion of the lungs; so that this author was led to class them as the results of real inflammation, which he called *pneumonia agonizantium*. (Op. cit. p. 241.) In these remarks he is confirmed by Louis. (Recherches sur la Phthisie, p. 30.) Whilst, therefore, we are led to recognise softening of the parenchyma as the pathological result of hyperæmia or sanguinous congestion, we find in it no distinction between active idiopathic inflammation and that congested state of lung which supervenes, in some measure mechanically, on an obstructed state of the pulmonary circulation.

The second stage, *hepatization*, (the red softening of Andral,) has very distinctive characters. A lung in this state is solid and elastic to the touch, of the consistence and weight of liver, and portions of it sink in water: it is no longer crepitous, neither does it, when cut, yield bubbles of air, but when pressed, a bloody fluid exudes sparingly from it. Its friability is generally greater than in the first stage, the fingers readily breaking through its substance; and if a portion be pressed between the fingers, it is reduced to a red homogeneous pulp. A hepatized lung appears to be more voluminous than is natural, but this depends on its being solid, and not collapsing, as a healthy lung does, on opening the thorax. Externally its colour is seldom so deep as in the first stage, and when cut into, it is also lighter, presenting shades varying from a blood or livid red to a light pinkish purple or colour of muscle, and various degrees of these colours are sometimes seen mottling the lungs so as to resemble some kinds of marble. Scattered through the hepatized portion various lines are visible, of a lighter colour, and specks almost white; a close examination discovers the former to be portions of the interlobular septa, less affected with inflammation, and the latter sections of bronchi or blood-vessels, whose coats have entirely escaped. There is generally in a hepatized lung another character, which becomes apparent on a close inspection, and more plainly with the aid of a lens. On a portion being cut, a number of little points can be distinguished, looking like grains of a somewhat lighter colour than the intervening spaces; and if the surface be wiped or lightly scraped, these grains appear slightly elevated, as if they consist of a more solid material. They may be made still more obvious by tearing the hepatized lung; they are then seen as little ovoid bodies, and may be detached singly from the tissue. In most instances these grains are closely pressed together so as to constitute the chief substance of the diseased part; but sometimes there are interstices of a darker colour, and in some cases the granular appearance is entirely absent. This uniform non-granular solidification of the lung, described by Andral (Path. Anatomy, vol. ii. p. 510,) and Chomel, (Dict. de Méd. t. xvii. p. 237,) is not recognised by Laennec, who considered the granular appearance as an essential character of hepatization; but from having seen the condition observed by the other authors as an indubitable result of inflammation, we do not hesitate to describe it as a variety of hepatization. This state of the lung differs from common hepatization in the absence of the granules, and a consequently darker and more uniform texture: it is sometimes softer, and bears a considerable resemblance to the substance of the spleen, whence it has been called *splenization*. In appearance it resembles that condition of the lung produced in pleuro-pneumonia, called by Laennec *carnification*, which we shall allude to hereafter; it differs, however, from this in being more friable. Andral was, we believe, the first writer who ascribed the granular appearance of a hepatized lung to the individual vesicles; and in this opinion he is followed by Laennec and Louis. In the second volume of his "Clinique Médicale," (p. 312) he describes the inflammation in pneumonia as occupying the air-vesicles, the internal surface of which secretes a viscid mucus, which, accumulating so as to fill their cavities, produces the granular bodies in question. In confirmation of this opinion, Louis asserts that this appearance can be imitated by gently injecting the bronchi. (Recherches sur la Phthisie, p. 9.) Laennec says that these little bodies "are evidently air-cells converted into solid grains by the thickening of their parietes and the obliteration of their cavities by a concrete fluid." (Transl. p. 201.) Many minute examinations which we have made of hepatized lungs have convinced us that the granulations contain no viscid mucus, nor does their appearance by any means confirm the opinion of Andral. They appear rather to consist simply of the little bunches of vesicles, (in which, according to Reisseissen, each minute bronchus terminates,) whose membranous tunics have become so swelled by the deposition of a soft albuminous matter in them, as well as from the increased size of their blood-vessels, that their cavities are obliterated. Both from the uniformity of their appearance when examined, and from the absence of any such matter in the sputa before death, we have long doubted that there is any effusion into the cavities of the air-cells, as supposed by Laennec; and Andral, in his latter work, seems to take a somewhat similar view, which he illustrates by the appearance presented by an inflamed lung when carefully dried. When the lung is in the first stage of inflammation, "the only morbid appearance it presents when dried is a reddish, yellow, or brown tinge in the parietes of its capillary bronchia and air-cells; and in

some cases even this shade of colour is wanting, and the lung, which before being dried presented a remarkable degree of congestion, when dried differs in no respect from a healthy lung. When the experiment of drying is tried on a hepatized lung, the parietes of the capillary bronchia and of the air-cells present invariably a red colour, and are, moreover, considerably thickened, so as to cause in some points a remarkable diminution, and in others a total obliteration of their cavities." (Path. Anat. vol. ii. p. 511.) The same sagacious pathologist refers the absence of granulations in the variety of hepatization before described to the greater degree of tumefaction which the air-cells undergo, by which they are approximated so closely as to be confounded together. This explanation does not seem to accord well with the darker hue of this varicty ; and we are inclined to hazard the opinion that the inflammation and swelling are in this case chiefly in the vessels and interstitial tissue between the cells and the bronchi, without involving the membrane which principally constitutes these cells, and which analogy would point out to be of the nature of mucous membrane. We propose this explanation merely as a question, and it is one of some interest ; for if it should be confirmed by further observation, it would open a more important inquiry whether such variety in the seat of the inflammation is distinguished by any peculiarity in the pathological history of the disease. The discrimination between the minute elementary tissues of the alimentary canal, in relation to disease, has not been without its practical utility ; and there can be little doubt that inflammation of the lungs would exhibit some variation in its signs or course according to the parts of the parenchyma which it affects.

[The average weight of the healthy lung is about 235 grammes. M. Grisolle (*Op. cit.*) has found the organ, in the state of red hepatization, to weigh 2500 grammes,—considerably more than ten times the natural amount.]

The advance of a hepatized lung towards the third stage is marked by its becoming lighter in colour and less humid. The change in colour seems to be produced by a substitution of more of the yellowish white semi-solid albumen for the red particles in its substance, by which the deep red or dull red of hepatization passes into a salmon-colour or a dingy pink, variously marbled in the degree of its progress, as well as by the mixture of black pulmonary matter. It is at this period that a hepatized lung attains its greatest degree of solidity ; when gently pressed, a turbid red liquid exudes scantily from it : very little additional pressure crushes its substance into a thick pulp ; for although its compactness is increased by the effusion into its substance, its molecular cohesion is greatly diminished.* A close inspection will generally discover that the granulations are the lighter points, and sometimes minute yellowish-white specks can be discerned in them, which are the first development of pus.

The lung affected with the third degree of inflammation, or rather its third effect, purulent infiltration, presents a still further change of character. It generally changes the red tinge for a yellowish drab or stone colour, which is still varied with red in parts less advanced, and with grey, blue, or bluish green, from the admixture of black pulmonary matter.† At first the lung retains the weight, compactness, and granular texture which characterize hepatization, the change being confined to the colour; whence this state has been called yellow hepatization, *hépatisation grise*, and by Andral, *ramollissement gris*,‡ from its increased friability. On cutting into it, no matter exudes in this early stage of suppuration, because the cohesiveness of the texture is still sufficient to retain it ; but very slight pressure reduces it to a thick purilage, in which pus obviously constitutes a principal part. In a more advanced degree the colour is of a straw or sulphur yellow, which begins in patches and spreads through the mass : on cutting into the lung, no granular texture can be seen ; but a yellowish, opaque, purulent matter oozes in greater or less abundance, according to the progress which the suppuration has made. The solid matter obviously diminishes as the pus is secreted ; for after squeezing this out, what remains in the hand is a mere debris of the pulmonary tissue, with a few granulations in which the suppuration has not advanced. Except in particular cases, the matter thus formed has a much fainter odour than that from an ordinary abscess. The softness of the lung in this state is so great, that even the slight pressure of a finger readily makes a cavity, which immediately fills with pus ; and both Laennec and Andral remark that this may be inadvertently produced in the course of examination, and mistaken for an abscess. In the most advanced stages of purulent infiltration, a lens will sometimes enable us to perceive that the only remnant of texture is a course irregular network, composed chiefly of vessels, bronchi, and the septa of lobules.

The purulent infiltration just described is the form of suppuration to which pulmonary inflammation tends ; the matter is rarely collected in a focus, and still more rarely in an encysted abscess. Laennec and Andral have recorded a few instances

* This character led M. Andral to call hepatization *red softening ;* but the objectionable nature of this term is sufficiently apparent from the fact that Laennec misunderstood its meaning (op. cit. p. 206, note) ; and Chomel described the state in question as a hardening of the lung (*endurcissement rouge*, Dict. de Méd. loc. cit.) Andral meant *friability*.

† These appearances are beautifully and faithfully delineated in the first number of Dr. Hope's coloured illustrations of morbid anatomy, the inspection of which will be more instructive to the student than any verbal description ; see especially fig. 4. From the blue shades which slight admixtures of the pulmonary matter produce, Dr. Hope supposes that this matter is sometimes blue : we believe, however, that this colour depends on a property which all whitish semitransparent bodies possess of transmitting the yellow and red, and reflecting the blue rays, so that, when the light transmitted through a thin transparent film is absorbed by a dark body under it, the blue rays are reflected from the film. Nothing illustrates this more perfectly than opal glass, through which dark objects appear blue, and light ones orange ; and an example of the same optical effect more in point may be given in the superficial veins, which through the skin appear blue, although they contain nearly black blood.

‡ This word *gris* is not here to be translated *grey*, a mixture of black and white, but *drab* or stone-coloured, like light brown paper, which in France is called *papier gris*.

where the suppuration had in one part become complete, and contained pure pus, whilst the adjoining parts were in a state of purulent infiltration quite diffluent on the margin of this sort of abscess, but firmer as they receded from it. This event has generally occurred in cases of partial peripneumony; and it appears to be no more than a completion of the process of suppuration, of which ordinary infiltration is only the beginning. The reason assigned by Laennec is probably correct;—that abscess of the lung is rare, because cases of partial peripneumony usually yield early either to nature or art, while an affection of greater extent produces death before the tissue can be removed by absorption. He cites a case in which a cavity lined with a strong false membrane, and capable of containing a pint and a half of fluid, existed in the middle of the right lung; the pulmonary pleura was destroyed to the extent of more than six square inches, and the wall of the cavity on this side was formed by the costal pleura, which adhered closely to the lips of the excavation. Several bronchial tubes opened into this cavity. (Op. cit. p. 208.) As there were no signs of tubercles, Laennec considers the cavity to have been caused by an abscess. A similar case occurred to Dr. Chambers at St. George's Hospital, and the lung is preserved in the museum there. A case of encysted abscess was shown to the Academy of Medicine by Dr. Honoré in 1823. It was filled with pus, as large as a middle-sized apple, and surrounded by a hepatized state of the lung. The general testimony of the latest pathological anatomists is in support of the opinion of Laennec, that the termination of pneumonia in abscess is of rare occurrence. Broussais says that he only met with it once; and in this case the inflammation was produced by a musket-ball, lodged in the lung for six years. (Hist. des Phlegm. Chron. tom. ii. p. 111.) Andral considers it extremely rare, and questions the accuracy of Laennec's statement, that in the year 1823 he met with more than twenty cases of partial peripneumony terminating in abscess. If we compare these opinions with the writings of Morgagni, Baillie, or, in fact, any writer on morbid anatomy prior to the last twenty years, or with the notions of the less informed of the present day, we shall be surprised at their discrepancy with the frequent mention of abscess of the lungs by these latter. The common error has been to mistake tubercular vomicæ, which are of very common occurrence, for abscess; and it is not always easy to avoid the mistake, even in the present state of our knowledge. Laennec says that tubercular cavities are to be distinguished by their containing some remains of the tubercular matter, or by the coexistence of tubercles in other parts of the lungs; but these remains may have been eliminated; and where a rounded vomica, containing only pus, is found singly in an inflamed lung, it may readily be mistaken for an abscess. Such examples show how uncertain are the anatomical distinctions between vomica and abscess; and perhaps any absolute boundary between these lesions is not to be met with in nature. We may recur to this subject when speaking of chronic peripneumony.

Abscesses of the lungs have sometimes been met with unattended with any marks of inflammation; the pus being apparently secreted in some other part of the system, is merely deposited in the lungs. We remember to have seen several abscesses of this kind in the lungs of a woman at the hospital of La Charité at Paris, who died with diffuse cellular and venous inflammation and suppuration of the leg and thigh. They were small, round, full of pus, and lined by recent coagulable lymph, the adjacent pulmonary tissue being quite crepitant. The liver, the spleen, and one of the kidneys presented similar abscesses in their parenchyma. Many other examples are on record of both circumscribed deposits and infiltration with pus after great surgical operations, (*Andral*, Path. Anat. vol. ii. p. 540. Dr. Hope's Illustrations, &c. part i. fig. 10, 11, 13); but as these are not connected with pneumonia, we need not describe them here.

Gangrene of the lung is rarely a consequence of inflammation. That it is so at all is questioned by Laennec, who considered this lesion as idiopathic, like hospital gangrene or anthrax, and as exciting rather than following the inflammation, which he says is by no means of an intense kind. It has, however, been fully proved that gangrene of the lung does occasionally succeed to inflammation of the organ, although, as in the case of abscess, it likewise occurs independently of it. Inflammation may be so intense as to destroy the vitality of a part, as mechanical injuries or chemical decompositions do; and of the occurrence of this event in the lung, there are a few instances on record. (*Andral*, Clin. Méd. t. ii. p. 295. Dr. Hope's Illustrations, part i. fig. 4.) As a consequence of acute inflammation, gangrene is commonly diffuse, surrounded by purulent infiltration or hepatization, and bounded by a deposit of lymph. The colour of the gangrenous part is a greenish brown, a dirty olive, or a dark brown, which a certain admixture of purulent and black pulmonary matter in some parts changes into a greenish grey. It is about the consistence of the lung in the third stage, except in some points where the sphacelus is more advanced and diffluent, and a turbid or greenish sanies runs readily from it. It is, however, the putrid fetidity which most distinguishes gangrene, and this test enables us to discover the presence of slight degrees of gangrene where it is not sufficiently extensive to affect the colour. Where the tissue is in the third stage, the colour as well as the odour readily characterizes it, but the hepatized lung bordering on gangrene can only be detected by its odour. We have sometimes found portions of hepatized lung very fetid, and although not materially altered in consistence, and only a little darker in colour than usual, we have been induced to think that the gangrenous process had commenced in them. M. Chomel describes a gangrenous condition of the lung, which is seen in the bodies of those who have died after some days' illness in consequence of being exposed to the effluvia of cess-pools or sewers. The lung is found almost black or greenish, full of a sanious, greenish, and extremely fetid liquid, softened in many places, and in some falling into deliquescence. Chomel thinks this lesion marks the passage of the first stage of inflammation into gangrene. The same

pathologist supposes the possibility of a whole lung being destroyed by gangrene in the case of its being compressed and rendered impermeable to air by an extensive pleuritic effusion; and he quotes a case, which he conceives to be of this kind, from the *Opuscula Pathologica* of Haller, in which the left lung had entirely disappeared, and the pleural sac was filled with a quantity of fetid albuminous liquid, in which the large vessels and bronchi terminated as if they had been cut off. (Dict. de Méd. t. xvii. p. 240.)

Circumscribed gangrene, if the result of inflammation at all, follows only the chronic kind; being apparently caused by the obstruction to the circulation which chronic inflammation sometimes produces in the lung. This form of gangrene more frequently occurs independently of inflammation, as the result of various septic influences present in the system, and answers more exactly to Laennec's opinion respecting pulmonary gangrene in general. For an account of the relations of gangrene to these causes and to inflammation, we refer the reader to the article MORTIFICATION.

We have hitherto described the general type of the several consequences of inflammation of the lung as detected by anatomical investigation. It remains for us now to notice the different varieties which individual cases present with regard to combination, extent, and complication of these inflammatory lesions.

Pneumonia is called *lobar*, *lobular*, or *vesicular*, according as it affects whole or continuous parts of lobes, or certain polygonal subdivisions of these, or single bunches of vesicles. Lobar inflammation is the most common, and may be limited to an irregular portion of a lobe, or it may involve a whole lung, or a great part of both lungs. When the inflammation is extensive, it is commonly found in different degrees of advancement. The most frequent of these combinations is the engorgement or first stage, with the second, hepatization; and the gradual transition of one into the other may here be very distinctly seen. The greatest advancement is commonly at the lower parts and margins of the lobes, (which are, according to Laennec, the most usual seats of peripneumony,) where we have the solid, airless, liver-like state of the second stage. In receding from this towards the less inflamed portions, the lung is more livid, softer, and moister, but still does not crepitate on pressure, and, except in some spots, does not pit, but breaks under the finger. Further still, there is some crepitation, but the lung feels heavy and yielding to the touch, and is of a dark red colour. In the slighter degrees of inflammatory engorgement, the colour is brighter and the crepitation more distinct, and the serum that flows on incision is very frothy. There is frequently around the inflamed part an œdematous state of the tissue, the colour of which is natural, but a yellowish frothy serum flows from it on incision. The third stage can also generally be traced in progressive degrees from the hepatized portions, lightening them by marbled shades of a paler or yellower hue, which sometimes take the shape of the polygonal lobules, and sometimes pass continuously over the interlobular partitions without distinction. Where these transitions of colour are abrupt, and mottled with black pulmonary matter, there is produced that appearance which Laennec compares to some kinds of granite, with its red and yellow felspar, grey quartz, and black mica. Combination of these three degrees may affect the whole of both lungs; and this to the extent that the whole of one lung, and more than half of the other, are solidified; but it is obvious that they cannot be so far involved in the second or third degrees, as life must be destroyed long before they could be rendered so totally impervious to air.

The anatomical evidence as to the parts of the lung most frequently affected by pneumonia is not entirely in accordance with that furnished by clinical observation. Hence we find Morgagni, Frank, and Broussais, who draw their conclusions from dissections, assign the upper lobes as the most frequent seat of inflammation; while Laennec and Andral, who included cases of recovery in the calculation, found the lower lobes to be most commonly inflamed. The reason of this discrepancy is, that inflammation of the upper lobes is the most frequently fatal; hence Chomel, although out of fifty-nine dissections he found the inflammation occupying the apex in thirteen, the base in eleven, and the whole or central parts in the other cases, does not withhold his assent from the decision of Laennec. That the right lung is more frequently inflamed than the left, is agreed on by all writers, and is proved equally by examition of the physical signs and by dissection.

[From the combined observations of several distinguished pathologists, it would appear, that in 1430 cases, the right lung was concerned in 742; the left in 426: and in 262 the pneumonia was *double*, or affected both lungs. It is probable, however, as has been suggested by Dr. Stokes, (*On Diseases of the Chest*, 2d Amer. edit. p. 272, Phil. 1844,) that the proportion of cases of double pneumonia is under-rated in this estimate. It is very much more common in young children, and in old persons, than in adults. Of 128 cases, observed in infancy,—according to MM. Valleix and Vernois,—the disease occurred in the right lung in 17 cases; in the left, in no case; and the pneumonia was double in 111 cases. Of these 111 cases, the disease predominated on the right side 59 times; on the left 10 times; and in 42 cases it was equal on both sides. (Rilliet and Barthez, *Traité Clinique et Pratique des Maladies des Enfans*, tom. i., Paris, 1843.)]

Inflammation not unfrequently attacks single, or a few isolated lobules, being abruptly limited by the interlobular cellular tissue, so that lozenge-shaped or polygonal patches of red, engorged or hepatized tissue are found in the midst of healthy structure. The same distinction is sometimes exhibited in the degree to which the inflammation has advanced, some lobules of light, purulent infiltration appearing in a livid engorgement. The inflammation in lobular pneumonia seems to originate in several points at once, and not to be sufficiently intense to traverse the barrier of the interlobular membrane. It is this form that supervenes frequently to great surgical operations or severe accidents, and it is common in children.

Andral has distinguished another variety of acute peripneumony, which, as he supposes it to affect individual air-cells or vesicles, he calls vesi-

cular. This presents itself to the anatomist in the form of little red spots, varying in size from that of a pin's head to that of a hemp-seed, and in colour from blood red to livid red: they are often more fragile than the rest of the tissue, which is sometimes quite healthy, but in many instances contains the miliary granulations of Bayle. This form of inflammation is not common, and requires a light colour of the lung to make it distinct; but we have observed it sufficiently to enable us to follow M. Andral in recognising it as a variety.

A considerable variety in the anatomical character of pneumonia is produced by the age of the subject. The lungs of young children are naturally more membranous and vascular than those of adults; and from this circumstance, and because the bronchi and vesicles are smaller, the texture is less light and crepitating to the feel. These characters are to be borne in mind when it is examined in an inflamed state, for they render the absence of crepitation and lightness, produced by this lesion, less apparent than in the adult. On the other hand, the colour, naturally light, of a pink, buff hue, makes the red appearance of inflammation more visible at this age. Pneumonia is seldom found so far advanced in children as in the adult. After many days' duration, it is often found only in the first stage, and its existence for weeks frequently does not bring it beyond the stage of hepatization. The division of the lungs into lobules is more apparent in children, and in the young of all animals than it is afterwards; which fact is an example of the progressive incorporation of elementary parts, which marks increasing perfection in the scale of organization. This anatomical difference appears to be the cause of the frequency of the lobular form of pneumonia in early life, and of the greater immunity from the inflammation which the interlobular texture often exhibits. The margins of the lobes are not uncommonly the only portions found hepatized in the lungs of children who have died of pneumonia supervening on hooping-cough.

[Instead of lobular pneumonia being confined to a single lobule, it often extends over many, constituting what has been termed *lobular pneumonia generalized*. As in the pneumonia of the adult, the morbid appearances may be divided into three stages. In the first, according to MM. Rilliet and Barthez, the cut surface of the lung is marbled with spots of a greyish rose, and red colour; these spots are more or less circumscribed, and are more readily torn than the healthy tissue, but they float in water; yield liquid, mixed with air, when pressed; and still crepitate. The *second* stage is the one most commonly met with, and resembles the hepatization of the adult; the *third*, or that of suppuration, requires careful examination to detect it—the substance of the lung having regained the greyish colour which belongs to its healthy state; but, by careful attention, some lobules are observed more prominent than the rest: they are not flaccid, like those around them, and, on pressure, they discharge a purulent fluid.

The appearances left by vesicular pneumonia may readily be confounded with the effects of phthisis. They have been accurately described by MM. Rilliet and Barthez. The lung is soft and flaccid, and is more or less collapsed, according to the extent of the lesion. Its section presents a great number of granulations of a yellowish-grey colour, and of about the size of millet-seed. These granulations differ in physical properties, as well as in nature, from crude miliary tubercles; the former containing a liquid—the latter forming solid masses. If the former be divided, they collapse immediately, giving issue to a drop of puriform fluid. MM. Rilliet and Barthez propose the term *vesicular bronchitis*, which, they think, expresses the nature of the affection better than its usual name, *vesicular pneumonia*. They consider the disease to be seated exclusively in the extreme bronchia; a certain number of pulmonary vesicles becoming inflamed, filled with pus, and dilated, without the surrounding cellular tissue being implicated. It is not easy to see, however, how these minute tubes can be inflamed to suppuration, without the inter-vesicular cellular tissue being more or less concerned. This, indeed, as elsewhere said, (*Practice of Medicine*, i. 397,) is, probably, the mode in which lobular pneumonia is produced.]

In old people, the prevalence of the black, pulmonary matter, and the rare, light, and often emphysematous texture of the lung, affect the character of the inflammatory appearances, the first two stages being darker and more dingy in colour, and the structure more readily disorganized and infiltrated with pus. Hence, whilst in children we see the suppurative process retarded by the density of the structure and the compactness of the effusion, in old people we sometimes find pus secreted in the second and even in the first stage before the red particles are removed; and this confusion of degrees is the more common where the pneumonia is of the congestive kind, as in typhous fever. Dr. Hope has given a drawing of a portion of lung from an old woman who died of typhous fever, which exhibited all the physical characters of purulent infiltration except the colour, which was a deep opaque chocolate. He says that he has frequently met with this state in the peripneumony of exhausted and cachectic subjects, especially after typhous fever.

Before describing anatomically some remarkable complications of pneumonia, we would stop for a moment on the question — what is the essential seat of pneumonia? Some pathologists, and among them Andral, place it in the air-vesicles and minute bronchi; others consider it to be in the interstitial cellular texture between these; whilst a third opinion supposes it to occupy all these indiscriminately. The writer, some years since, thus expressed his opinion: "Our knowledge of minute anatomy does not permit us to specify with certainty the exact and essential seat of this inflammation; but I am disposed, from a consideration of the signs and of the effects on the tissue, to refer it principally to the plexus of vessels and submucous tissue surrounding and uniting the minute extremities of the bronchi. It may, and usually does, extend to the mucous membrane of these extremities, and of the smaller bronchial tubes; but this is, *strictly* speaking, rather a bronchitus attendant on the parenchymatous in-

flammation, than a part of the pneumonia."* We have, since writing this, made many minute examinations of the lung in various forms of inflammation, and if they tend at all to modify this opinion, it is to the effect that the plexus of capillary vessels rather than any distinguishable texture, is the essential seat of pulmonary inflammation. On inspecting, by the aid of a simple lens, the margin of a slightly inflamed spot of lung, numerous vessels may be seen, distended with blood, passing across, around, and between the vesicles, with very little regard to their form or disposition; and as the scrutiny is extended to a part more inflamed, these vessels are so multiplied and confounded with each other as to be no longer separately discernible. In this state it is impossible to distinguish whether the tunics of the cells, or the tissues which connect them are most affected, for they all appear one mass of redness, in which are seen the cells irregularly diminished in size, and containing bloody serum with bubbles of air. The interstitial cellular texture, where it can be separately discerned, namely, between the lobules and around the larger bronchi, is generally less vascular and of a lighter colour than the other parts, and in some instances appears to be nearly free from the inflammation. The lining membrane of the minute bronchi, although generally of a deep red colour, is sometimes bluish red, as if from redness under it rather than in it; and on tracing these tubes higher, the presence of this inflammatory character is very uncertain. These examinations and some pathological considerations induce us to consider the capillary ramifications of the pulmonary artery and veins to be the proper seat of pneumonia, and that these may involve more or less of the tissues through and around which they pass. Thus through them the tunics of the air-cells, particularly the sub-mucous, commonly become the seat of inflammation; whence are formed the granulations of ordinary hepatization. When, again, the inflammation is confined more to the inter-vesicular plexus and tissue, which appears to be the case in the more congestive form of inflammation, where vessels larger than capillaries are involved, the uniform non-granular form of hepatization which we have before described, is produced.† If, as is commonly the case, the inflammation extends to the extremities of the bronchial arteries, which are said by anatomists to anastomose with the pulmonary, the mucous membrane lining the vesicles and minute bronchi partakes of the inflammatory action, and exhibits it in the manner peculiar to mucous membranes by the secretion of a viscid mucus, and afterwards of pus. So, likewise, when the inflammation reaches the surface of the lung, it is generally, but not constantly, propagated to that portion of the pleura which invests it and derives its vessels from it; and this extension of the inflammation may add another character to such instances of the disease. But it is its seat in these extensive capillaries of the lungs through which the blood of the whole system is continually passing,—it is this affection of so considerable and important a portion of the circulatory system that causes the severe and intense character of pneumonic inflammation; and the more constantly we hold this in view, the better shall we understand the pathological history of the disease, and its important relation to remedial measures.

We have just mentioned the extension of inflammation to the pleural covering of the lung; this occurs so frequently that some writers have used the terms pneumonia and pleuro-pneumonia as synonymous. But in the ordinary cases of pneumonia the pleuritic affection is so slight that it scarcely modifies the disease, and like the inflammation of the bronchi, which is as usual an accompaniment of pneumonia, is to be viewed as incidental rather than essential in the disease. In these cases the pleuritic inflammation will show itself to be modified by the seat and extent of the pulmonary disease. When this is partial, that portion of the pleura which covers it has upon it an albuminous deposit, which is generally thin, and if the disease has been of sufficient duration, shows signs of organization. The corresponding portion of the costal pleura frequently presents a similar deposit; an instance of that propagation of inflammation by contiguity which seems to assimilate the proximate cause of inflammation to something more subtle and mobile than the common properties of texture, and to bring it into close analogy with electric agencies. These albuminous effusions are the basis of false membranes, which form adhesions between the lung and the costal pleura. Underneath them the membrane exhibits points and patches of red, as in ordinary pleurisy. When the pulmonary inflammation is of small extent, there is commonly a small sero-purulent effusion into the pleural sac; but extensive hepatization prevents this from taking place, by filling the pleural cavity with its own unyielding substance, and the lung is then partially covered with a thin false membrane, which is thicker along the edges, in the inter-lobular fissure, and occasionally at some points where the inflammation was first extended to the pleura. (Transl. of Laennec, p. 487.) These circumstances prove the greater intensity of the pulmonary inflammation, and constitute the reason given by Laennec for not calling such a complication a true pleuro-pneumony.

There is another remarkable combination of pleurisy and pneumonia, in which the former, with an abundant liquid effusion, has the predominance, and signally modifies the effect of the inflammation on the tissue of the lung. The pneumonia is generally circumscribed, sometimes lobular, and is often seen in several distinct spots at the lower parts of the lung. Laennec describes the hepatization under these circumstances to be much more flabby and less solid than in simple pneumonia. It is of a red or livid red colour, and destitute of granulations or other trace

* A Rational Exposition of the Signs of Diseases of the Lungs and Pleura, by Charles J. B. Williams, M. D. 1828, p. 80.

† An uncommon effect of pneumonia has, since writing the above, been brought under our notice by Dr. Stokes, in a recent number of the Dublin Medical Journal. A part of the lung was in the third stage; and the suppuration, instead of prevailing most in the tunics of the bronchi and vesicles, had scarcely affected them, but had destroyed the interstitial tissues, so that the vesicles presented the appearance of bunches of little grapes or berries. We need not remark how much this fact confirms the view which we take of the occasional diversity in the principal seat of pneumonic inflammation.

of air-cells; but the vessels and bronchial tubes are still conspicuous in it. It contains no air, and not more moisture than muscle; from its resemblance in compactness and suppleness to this tissue, Laennec distinguishes it by the term *carnification*. In a case of this kind, which we have recently seen, we could not but recognise in this carnified state of the lung the uniform, non-granular hepatization which we have described as that in which the interstitial plexus and tissue are the only seat of the inflammation; and this variety of consolidation, which is arrested or restrained by the pressure of the pleuritic effusion, appears to be another proof that the essential seat of pneumonia is not in the air-cells. It exhibits the essential effects of pneumonic inflammation in colour and solidification, without the granulations and humidity which are fortuitous and dependent on effusion extending to the walls of the yielding air-cells. As it might be expected, the progress of this form of pneumonia is slow, and rarely reaches the suppurative stage; but Laennec says that in subjects who had died in from one to three weeks after the subsidence of inflammatory symptoms, he has found "the affected portions of the lung flabby, dry, and yellowish, with the vesicular texture discoverable in some places, but the vesicles apparently filled with a half concrete pus." It has been remarked by Dr. Stack that this compressed state of the lung is sometimes perpetuated by false membranes, the product of the pleurisy, binding it down. (Dublin Hospital Reports, vol. iv. p. 90.) This we have seen exemplified more than once: in one case illustrative of such an effect of a false membrane, a pneumothorax had supervened on the absorption of the liquid effusion. (Rational Expos. &c., p. 143.)

Laennec calls that only true pleuro-pneumonia in which both diseases are extensive, there being copious pleuritic effusion, with a considerable extent of peripneumonia. Such a combination is of rare occurrence, and as there is only a difference of degrees, it does not appear why this alone should be entitled to the compound name.

The anatomical characters of resolution or cure of peripneumony are worthy of remark; they are particularly described by Laennec. When recovering from the first stage, the pulmonary tissue becomes drier and more filled with air, but for some time retains its red colour, as if dyed. Sometimes the texture continues for a while to be œdematous. A hepatized portion in progress towards cure assumes a paler hue, passing through shades of red grey and reddish flax colour, until it become a little redder only than natural. The texture at the same time becomes more yielding and moister, containing a frothy serum, which abounds more and more in air as the resolution advances, the granulations giving place to the development of the air-filled vesicles. These changes begin at several points, and, when advanced, often leave others still hepatized. When the tissue resumes its natural dryness and colour, it remains firmer, more elastic, and heavier for some time after. The first signs of restoration from the third stage are the yellow tinge becoming lighter, and the pus more liquid by the intermixture of serum; air-bubbles afterwards appear and continue to increase, while the pus is reduced to small specks. As the vesicular texture returns, it resembles the first stage of engorgement in all respects but colour, which appears on incision to be dirty yellow or greenish, and this continues even after the complete reabsorption of the serum The anatomical history of the process of cure of gangrene of the lungs will be found in the article Mortification.

III. Pathological History of Pneumonia.

Operation of Causes. — Pneumonia is the most frequent of all the parenchymatous inflammations. This in part proceeds from the very vascular structure of the lungs, which renders them very susceptible of inflammation; but we also see a reason in the nature of their function, which peculiarly exposes them to suffer from the various influences that injure the balance of the circulation. Whatever view is taken respecting the generation of heat, it is sufficiently established by experiment that the function of the lungs is intimately connected with it, and that the application of any cooling influence to the body makes a demand on an increased activity of this function. As, under such influence, the blood returns freely to the lungs in a state more highly venous than usual, there is a greater necessity for respiration, and both this increased flux and the consequent augmented activity bring this organ into a condition peculiarly favourable to the development of inflammation. If the application of cold be not long continued, the pulmonary congestion may soon be removed by the due oxygenation of the blood, and consequent restoration of the balance of the circulation, before the tonicity of the pulmonary vessels has materially suffered; some minor part of the circulation, as that of the bronchial membrane, occasionally alone being the seat of inflammatory reaction. But if the cold be severe and long continued, if a large portion of the body, especially the chest, be exposed to it, the pulmonary vessels suffer not only from their increased task and the congestion consequent on its imperfect completion, but likewise from the sedative influence of the cold directly affecting them; hence, whenever reaction is established, they are the parts most likely to suffer from its effects. The manner in which excessive exertion and the inhalation of asphyxiating gases and vapours excite the disease is obviously likewise by the congested state which they occasion in the vessels, which, if sufficiently continued, only requires the addition of a subsequent reactive excitement to convert it into inflammation. Alcohol and its various compounds also act as occasional exciting causes of pneumonia by their narcotic influence on the nervous system, by which the sensation of want of breath that excites the respiratory act is blunted, and a congestion of blood takes place in the lungs in consequence of their insufficient action. How far in these several instances the stasis of highly venous blood in the pulmonary vessels may contribute to injure the tenacity of their coats, and thus to render them peculiarly obnoxious to the consequent reaction, is only a matter of conjecture, not unsupported by analogy.

The presence in the body of various poisons, as that of the rattlesnake and deleterious fungi, may lead to the production of pneumonia partly in the same way, but probably also from a speci-

fically injurious influence on the pulmonary vessels. There is no organ in the body so intimately exposed to the influence of the blood as are the lungs; the whole circulating mass passes rapidly through their fine vascular filter, and if there be a noxious ingredient in the blood, it may be reasonably expected here to show its effects. Hence the origin of pneumonia, not only from the poisonous influences just named, but probably also, as Laennec has surmised, from the more subtle ones of an epidemic nature. The inflammations arising in the course of various febrile and exanthematous diseases may owe their existence in some degree to a similar mode of influence; but the tendency of the phlogistic reaction to localize itself in parts predisposed to inflammation in many of these disorders, is likewise a link in the chain of causes, which must not be withheld from our recollection. In eruptive fevers particularly, it is common, as Andral has remarked, (Clin. Méd. tom. ii. p. 287,) to see a great degree of dyspnœa precede the appearance of the eruption, and generally cease, as if by magic, when this fully takes place. In some cases, however, and especially where the eruption recedes or is not fully thrown out, the dyspnœa continues, and assumes the character of a more permanent disease. This is obviously a congestion persisting and becoming converted by general vascular excitement into an inflammation. The deficient resonance of the chest, remarked by Avenbrugger and Corvisart at the commencement of eruptive fevers, is a physical indication of this pulmonary congestion.

The intercurrence of pneumonia with other inflammatory diseases of the lungs and neighbouring parts will admit of a more direct explanation: it is an extension of inflammation by contiguity, and arises from some additional external cause, as when bronchitis or pertussis becomes a pneumonia in consequence of exposure to cold; or from an additional internal movement, as when, in consequence of a checked excretion or a too well nourished mass of blood, such slight or membranous inflammation spread and infest the more considerable circulation of the parenchyma. The remarkable tendency which is exhibited among children to such a propagation of inflammation is dependent on the greater proportion of membrane and vascularity of the lungs, as well as on the higher activity of their function at that early age; facts pointed out by Magendie and Laennec, and strictly corresponding with the rapid progress of diseases of these organs at that period. The frequent intercurrence of pneumonia with hooping-cough appears to depend not merely on a propagation of inflammation; the congested state of the lungs induced by the cough and imperfect oxygenation of the blood has likewise its share in favouring the development of inflammation.

The metastasis of the inflammation of gout and rheumatism occasionally falls on the lungs, but seldom without some predisposition to disease in the organ, from previous attacks of inflammation; and there is nothing in these instances which tends to throw new light on this obscure point of pathology. Whether these, and likewise the cases of pneumonia supervening after severe accidents and surgical operations, noticed by Guthrie, Bell, Dupuytren, and others, are connected with an altered condition of the circulating fluids, is a question which cannot at present be placed on any other than the ground of conjecture.

Tubercles and apoplectic engorgements in the lungs may excite inflammation both by their irritating influence, and likewise, if they are numerous or extensive, by the obstruction which they occasion in the circulation, and which leads to the congested state which we have so frequently observed to favour the development of inflammation. The points adjoining tubercular excavations are likewise occasionally attacked with inflammation. It is to be remarked of these and other inflammations which originate chiefly from mere local irritation, that they are much less severe and permanent than those in which the system at large is more concerned, and the inflammation is as it were the focus of a general derangement. Accordingly it is observed that such intercurrent peripneumonies are commonly slight, and, if recognised, yield readily to treatment. But their latent character constitutes their worst feature, their symptoms being merely a slight exacerbation of those of the pre-existent disease; and unless detected through the aid of their physical signs, they may speedily prove fatal.

In reviewing the pathological relations of the causes of pneumonia, we cannot avoid noticing the important link which congestion of blood in the lungs forms in the development of the inflammation. In by far the majority of cases this congestion is immediately determined by the operation of the exciting cause, and precedes what may be termed the irritative stage of the inflammation. Such we have seen to be the effect of cold extensively applied, of violent and long-continued exertion, of certain poisonous influences, (which, by diminishing the sensibility of the nervous system, impair that sensation of want of breath which excites the respiratory act,) and of the congestive stages of various febrile diseases. The connection of congestion with inflammation is still more forcibly illustrated in the pneumonia of the moribund, in which the blood, imperfectly oxygenated through the failure of the respiratory forces, accumulates in the pulmonary vessels, which even then become the seat of inflammatory action, and if the agony or change of death be of long duration, produce those changes which are recognised as the results of ordinary pneumonia. This point has been fully established by Laennec and Louis. The latter found signs of partial inflammation in 22 out of 112 cases which died of various chronic diseases, and in which the inflammation could have existed only a few days before death. (Rech. sur la Phthisie, p. 39.) Laennec not only found proofs in the dead body, but likewise repeatedly discovered signs of this inflammation supervening during the failure of the powers before dissolution in various diseases. Seeing, then, the close relation which simple congestion, or passive hyperæmia, (as Andral terms it,) of the lungs bears to inflammation, so close that their anatomical distinctions cannot be discerned, it remains for inquiry what is the additional pathological movement which gives to inflammation its character and permanency, and renders it more than simple

hyperæmia. In answering this question by asserting that it is a reaction of the neighbouring arteries and of the heart, we only describe a phenomenon which does succeed and which is the next of a series of actions constituting the disease in question. This is the irritative stage, and is in most examples posterior to the formation of a congested state of the vessels. In some instances, however, as where inflammation succeeds to a wound or other mechanical injury of the lung or other irritation in its substance, the afflux of blood is posterior to the irritation, which is then the starting point of the pathological changes. In the article IRRITATION we have already described an afflux of blood as generally following an excitement of a part, and it does so the more certainly and fully in proportion as the organ is vascular and freely supplied with blood; hence the lungs are peculiarly liable to the congestion of irritation, and if the cause be applied for a sufficient length of time, this congestion may become inflammation. We do not here stop to trace the progressive changes and reaction which accompany the development of inflammation in general; these are sufficiently dwelt upon in the article on that subject; but in considering the lungs as an object of inflammatory action, it cannot escape our observation that their vicinity to the heart, their great congeries of vessels through which the whole blood of the body passes, their spongy and yielding texture, all tend greatly to increase the delicacy of the balance of their circulation, and render any disorder of this balance peculiarly liable to those reactive processes of the principal circulation which form a part of inflammation and fever.

Physical Signs of Pneumonia.—Through the aid of auscultation and percussion we obtain a better knowledge of the pathological process of pneumonia than can be obtained in any other way, for through their means we in a measure apply our senses to the very seat of the disease; but there is still some degree of doubt about the precise mechanism of certain of these signs, and this obscurity leaves us uncertain as to some minute points of the pathological progress of the disease, which we have already found not clearly determined by their anatomical history. We shall, however, describe the signs as they have been accurately observed, and afterwards state the view of the pathology to which they, together with the anatomical characters of the disease, appear most rationally to lead.

On the first invasion of inflammation of the lungs, contemporaneously with the earliest of the general symptoms before described, the ear unaided, or through the stethoscope, will perceive in some part of the chest a peculiar sound accompanying the usual respiratory murmur: it is a fine crackling or crepitating sound, like that produced when kitchen salt is thrown on a heated iron; or like the crepitation which occurs when a healthy lung is pressed between the fingers. A pretty correct idea of the sound may also be obtained in a readier manner by rubbing between the finger and thumb a lock of one's own hair close to the ear. This is the *crepitani rhonchus*, and was considered by Laennec to be pathognomonic of the first stage of pneumonia. The space where it can be heard is often at first very limited, sometimes not extending more than an inch or two; but when more advanced, it may occupy nearly a whole lung. The parts where it is most commonly first heard are, below the inferior margin of the scapula, below the axilla, or about the lower margin of the pectoral muscle, points corresponding with the lower lobes of the lungs, which, as we have before noticed, are the most frequent seat of inflammation; but it is occasionally met with in other parts of the chest. At the commencement of inflammation, the crepitation is merely an *addition* to the ordinary respiratory sound, which is still distinct; but as the disease proceeds, the crepitant rhonchus prevails more and more, until it is the only sound heard in that spot during the respiratory movements.

At this period the part begins to sound a little duller on percussion than the corresponding opposite point, particularly if this be practised mediately, with M. Piorry's plate, or even on one of the fingers of the left hand pressed closely on the chest. The progress of the inflammation is marked by the minute crepitations constituting the rhonchus becoming less continuous and regular, and being confined principally to the end of each inspiration; and as the lung begins to pass into the state of hepatization, they are heard only on coughing or on deep inspiration, and at last cease entirely. If the disease is extensive, in proportion as the crepitant rhonchus diminishes, the respiration in the sound part of the lungs becomes louder than usual, and like that of children, whence it is called by Laennec *puerile respiration*. In the second stage of pneumonia, if the disease is extensive, the sound emitted on the percussion of the part of the chest corresponding with the hepatized portion, is quite dull, and yields no more resonance than the region of the liver. On applying the ear, neither the ordinary respiratory murmur, nor the crepitant rhonchus of the first stage is heard; but sometimes another kind of sound is substituted for them, and this occurs most commonly in proportion as the hepatization approaches the middle parts and root of the lobes, and extends to the surface. This is a whiffing sound, resembling that produced by blowing through a crow's quill, and it is occasionally so loud as almost to amount to a whistle. This is the *bronchial respiration* of Andral and Laennec, and in its acute and defined character forms a remarkable contrast with the dull diffused murmur of natural respiration. It is often heard most distinctly during the forcible respiration of coughing. A peculiar resonance of the voice, called by Laennec *bronchophony*, is less commonly observed at the same points. The voice resounds at the end of the stethoscope in a modified tone, as if it came through little tubes. It does not, as in perfect pectoriloquy, appear to originate in the stethoscope, and it is not heard in distinct words, but in notes of various continuance, not always synchronous with the words uttered by the mouth, and at intervals is alternated with what may be called whiffs of the bronchial respiration. With these several sounds there is often mixed a mucous rhonchus or fine gurgling, but this seems circumscribed and does not obscure the others.

[M. Hourmann has pointed out another pheno-

menon which, as suggested by M. Chomel, (*Dict. de Méd.* 2d edit. xxv. 173,) might be useful in cases in which the feebleness of the patient's voice might not permit bronchophony to be heard, and which consists in a greater resonance of the observer's own voice, (*retentissement autophonique*,) when he speaks with his ear accurately applied to the chest opposite the seat of the hepatization. (See Auscultation.)]

The puffing or blowing sound of bronchial respiration sometimes gives the auditory sensation of a person blowing into the ear through a narrow tube; and as this sound is sometimes interrupted, and occurs in irregular puffs or whiffs, it gives the impression of a movable veil or loose curtain fluctuating under the impulse of the air.

[At times, solidification occurs rapidly, without being preceded by the usual signs,—the lung passing, in the course of a few hours, from apparent health, according to every physical sign, to solidification. Signs of sudden solidification, without preceding crepitating rhonchus, have been regarded pathognomonic of pleurisy with effusion, yet they are equally indicative of the condition just described. The principal diagnosis between this *typhoid solidity* and a pleural effusion, as remarked by Dr. Stokes, (*Op. cit.*), is, that with the dulness and absence of respiration accompanying a considerable effusion, the signs of excentric displacement are wanting; the heart is not displaced; the epigastrium and hypochondria are concave, and the intercostal muscles unaffected.]

In the third or suppurative stage, in addition to the dulness on percussion observed in the second stage, there is sometimes a coarse mucous rhonchus, heard especially at the root of the lungs or about the lower axillary or mammary regions: this is the only physical sign of the termination of the inflammation in this stage; and when it is observed to commence in a part where bronchial respiration and resonance have been previously heard, it may be taken as a pretty certain proof of the supervention of this change. Sometimes, however, the bronchial respiration and resonance continue without this sign, and there is then no physical indication of the occurrence of the third stage.

If the suppuration becomes complete, by the formation of an abscess in any portion of the lung, no physical indication of this event presents itself until the purulent matter has been partly expectorated. In that case a gurgling or cavernous rhonchus will be heard in the corresponding point; and when the evacuation of the liquid contents of the abscess has been further completed, this rhonchus will give place to the *hollow cavernous respiration* or *pectoriloquy*, indicating a cavity communicating with the bronchi. If, however, the abscess is very large, it may leave a cavity in which the *metallic tinkling or amphoric resonance* is produced, precisely as these phenomena are developed in phthisis after the evacuation of the contents of tubercular vomicæ. The gangrenous termination of peripneumony will announce itself by the putrid fetor of the breath and of the matter expectorated; and in case the gangrenous portion is detached, whether in a circumscribed slough, or in a diffused deliquium, the same signs of a cavity may be produced as in abscess of the lungs.

Such are the physical signs which the most accurate observers have concurred in attributing to peripneumony and its consequences in their simpler forms. We shall better understand their nature as well as the varieties to which they are subject, if we examine them more rationally, in relation to the other symptoms, and to the effects of the inflammation anatomically discovered in the tissue. With respect to the crepitant rhonchus, there can be no doubt that its seat is in the minutest order of bronchi and air-cells of the lungs, since it is only diseases which affect these parts that present this or any sound resembling it. But the precise manner in which they are affected in order to produce this sound is not quite so certain, and different opinions upon it have been entertained. M. Andral considers the crepitant rhonchus to be nothing more than a finer modification of the mucous rhonchus; the latter becoming crepitant when its seat is in the minutest bronchi and air-cells, the narrow dimensions of which render the bubbles which compose it finer and more equal. Hence he asserts that the crepitant rhonchus is produced by the intermixture of air and liquid in the air-cells and smallest bronchi in other diseases as well as in pneumonia, and that it occurs in acute bronchitis whenever the inflammation and excessive secretion extend to these parts. Although he absolutely denies the accuracy of this statement, Laennec does not appear to have clearly made up his mind as to the cause of the crepitant rhonchus of peripneumony. Speaking of this sound in one place, he says: Besides the sound of crepitation, a sensation of humidity in the part is clearly conveyed. We feel that the pulmonary cells contain a watery fluid as well as air, and that the intermixture of the two fluids produces bubbles of extreme minuteness."—"In respect of the size of the bubbles in the different rattles, they may be estimated as *very large, large, middling, small.* The last term is especially applicable to the crepitous rattle of peripneumony, in which it seems as if an infinity of minute equal-sized bubbles, formed at once, were thrilling or vibrating, rather than boiling on the surface of a fluid." (Dr. Forbes's Translation, p. 52.) In another place, however, he says that at the invasion of the inflammation, the crepitation "conveys the notion of very small equal-sized bubbles, and seems hardly to possess the character of humidity." (Op. cit. p. 212.) These opinions are equally inconsistent with each other, and with his observation on the certitude with which he strenuously insisted that simple acute bronchitis never presented this sign; for truly, if the intermixture of air and liquid in the minute bronchi were the only elements of the crepitant rhonchus, this disease as well as pituitary catarrh, which certainly present this condition, ought in an equal degree to produce this sound. Such, however, was the fine accuracy of Laennec's observation, (as, during the last year of his life when he was most perfect in his art, we had personally ample opportunities of proving,) that we do not hesitate to receive his testimony on this point as the most exact, whatever inconsistency may appear in his reasonings upon it; and therefore, although we cannot pretend to such a perceptive acumen as to be able always to distinguish the crepitant from the mu-

cous rhonchus in all their modifications and gradations, we assume the authority of the great auscultator as a proof in addition to others, that these two sounds are essentially different in their nature, and owe their characters to peculiarities in the mechanism which produces them.

It is agreed on by all auscultators, that œdema of the lungs and the margins of hæmoptoic engorgements may produce a rhonchus of the crepitant kind, and it naturally occurs to us that these lesions resemble pneumonic engorgement in the pressure to which they subject the vesicular parenchyma. If we compare with these instances the very close representation of the crepitant rhonchus which the simple pressure of a healthy lung will produce, we are led at once to an explanation of the mechanism of this sign. By this pressure the air is expressed from the tissue, whilst the tubes and cells are so narrowed by the pressure that it can only pass out of them in successive bubbles, the escape of each of which produces a minute crepitation: this sound Laennec tells us differs from the crepitant rhonchus only in being not so strong; here no preternatural fluid is present in the air-cells. In œdema, or in effusion of blood into the substance of the lungs, we have the interstitial effusion and narrowing of the minute air-tubes, and cells, and from the nature of the expectoration we may conclude that there is also an increase of liquid within them; the rhonchus that accompanies them is accordingly described by Laennec to consist of moister and somewhat larger bubbles than that of peripneumony, and he terms it subcrepitous. Lastly, we have the peripneumonic engorgement, in which anatomy assures us that there is the same narrowing of the air-tubes and cells by the swelling of the interstitial blood-vessels, whilst the observation of the sputa leads us to conclude that the interior of these tubes and cells is lined with a viscid secretion; this produces the drier and stronger sound of the genuine pneumonic crepitation. This is in principle the same explanation which we advanced some years since in the following passage: "The distended vessels, and the serous effusion in the interstices, press on the minutest brenchial ramifications, and partially obstruct the ingress of air into the cells to which they lead; whilst the viscid secretion of the mucous membrane simultaneously inflamed, filling the calibre of the tubes thus narrowed, only yields to the air in respiration forcing its way through it in successive bubbles. This bubbling passage of air through a viscid liquid contained in an infinity of tubes of equally diminished calibre, causes that regular and equable crepitation which constitutes the true *rhonchus crepitans*." (Rational Exposition, &c. p. 81.) We were led to doubt the accuracy of the explanation of Andral and Laennec, from the circumstance that the character of the expectoration in pneumonia does not countenance the supposition that there is during life any other secretion into the air-cells than the characteristic viscid secretion of the mucous membrane which lines them. In a former article we have pointed out the tendency which the natural respiratory movements have to throw all superfluous secretion from the smallest bronchi into the larger until they are brought under the influence of the act of expectoration. (See Expectoration.) Now if, as those who found their opinions solely on morbid anatomy maintain, there were a serous effusion into the air-cells in the first stage of pneumonia, there ought to be more or less of this serum mixed with the sputa as in some cases of pulmonary œdema: this is not the case, for the expectoration is a glutinous mucus from the onset of the inflammation, and instead of becoming more serous, increases in viscidity as the inflammation becomes more vehement. Moreover, we venture to follow the example of Laennec in asserting that there is a mucous or liquid rhonchus of the fine bronchial ramification, the character of which is sufficiently distinct from the rhonchus of pneumonia to merit its separation in kind as well as in degree from the latter sign. This fine mucous rhonchus, which we have observed in pituitary catarrh, and in the general bronchitis accompanying continued fever, occupying the base of the lungs, the common seat of the crepitant rhonchus, is distinguished from this latter in the greater inequality of the bubbles which compose it; they appear to roll through a liquid without breaking with that regularity which distinguishes the crepitation in pneumonia; there are, besides, little hissing or whistling sounds mixed with them, which convey to the mind the impression of a movable proportion of air and liquid in the tubes. If this mucous rhonchus is to be distinguished from the subcrepitant of pulmonary œdema and apoplexy, it is by the greater irregularity of the minute sounds which constitute it; but we cannot pretend to assert that this distinction is always possible from the nature of the sound, nor can we deny that there are gradations and combinations of the two rhonchi which entirely baffle our power of discrimination. But we do maintain that the crepitant rhonchus of peripneumony is, with few exceptions, sufficiently characterized by its pure equable crepitation, unmixed with hissing or any sounds of liquid, to render it a valuable and available means of distinguishing this disease in its earlier stages.

In conceiving the mechanism of this rhonchus according to the explanation given above, we must take into account the force with which the air passes through the narrowed tubes, and we shall then perceive why the bubbles crepitate drily, and the liquid is not carried before the air passing to and fro, as it would be were its viscidity less and its quantity greater. It has been asserted that the crepitation of peripneumony may be imitated by the bursting of bubbles on the surface of fluids of the tenacity of serum, and hence it is concluded that the crepitant rhonchus depends on the mixture of air with such a fluid in the lungs; but the cases are by no means analogous: in the one, the bubbles rise and burst merely from their own levity; in the other, an active moving force is constantly driving and breaking them through an infinity of minute tubes. On the whole, then, the more we have examined and reflected on the subject, the more we are convinced that the physical cause of the crepitation of peripneumony is the forcible passage of air through narrowed passages lined with a viscid liquid; and if we modify at all the explanation formerly given, it would be

that we have not the ground to confine the crepitation to the minute tubes only, but that it probably occurs in the air-cells likewise.

We can readily perceive how the various degrees of this rhonchus become an accurate measure of the progress of the inflammation. Thus, when this is most moderate, the air enters many tubes still without obstruction or crepitation, and the natural sound of respiration is heard together with the crepitant rhonchus; but when the narrowing of the tubes and cells and the viscid secretion lining them, become more universal in the part, no air enters there without this crepitation being produced, and this rhonchus is then heard pure and unmixed. The next change is the gradual diminution of these crepitations, owing to the increased swelling of the coats of the air-cells, or of the interstitial tissues. Anatomical investigation teaches us that at this period there is a deposition of a semi-solid lymph or albumen; this appears to cause such a successive obliteration of the tubes and cells as entirely to obstruct the entry of air into them. Accordingly, as the lung passes from the first stage of inflammation into the hepatized state, the crepitations become fewer, are heard only at the acme of inspiration, or during the forcible efforts of coughing, and at length cease altogether.

The physical cause of the bronchial respiration and resonance is more obvious. The deposition of albuminous matter in the parenchyma of the lung has the effect, as we have just seen, of obliterating the spongy structure, and converts it into a solid mass. In the healthy state, the different density of its materials (air, membrane, and liquid) prevents the transmission of sounds from the interior to the surface; but now that this density is rendered uniform, it propagates the sound of the air passing to and fro in the larger bronchial ramifications of the interior; and during the exercise of the voice, its resonance also traverses the hepatized substance in a similar manner. It is obvious, therefore, that the extent and intensity of these sounds must greatly depend on the number and size of the bronchial tubes involved in the hepatized portion; hence they are most distinct when the inflammation occupies the summit, root, or central parts of the lung, and extends to the surface; but when the lower, the central, or the superficial portions are alone affected, they may be altogether wanting. When the principal part of a lung is hepatized, including the central portions, which contain many considerable bronchi, a noisy resonance of the voice, almost amounting to pectoriloquy, is heard in the scapular region, in the central parts of the axilla, or about the lower margin of the pectoral muscle, but it may be generally distinguished from imperfect pectoriloquy by its more diffused character, and from that of the perfect kind by the indistinctness of the words uttered. The puffing or fluctuating sound of bronchial respiration and bronchophony, which we have mentioned as sometimes met with, is referred by Laennec to a thin portion of healthy and crepitant lung immediately on the surface and between the hepatized portion; and if this observation is exact, the cause of this irregular puffing seems to be the air entering or leaving this healthy portion, and thereby changing the degrees in which the sound from the interior is transmitted through it.

We have mentioned the supervention of a liquid mucous or gurgling rhonchus as the only physical indication of the occurrence of the third or suppurative stage. This sign is the proof of that softening and deliquescence of parts which mark the process of suppuration in all its forms, but we do not obtain from it any further light on the intimate nature of this termination of inflammation. The more liquid form of the expectoration generally corresponds with the presence of the mucous rhonchus; sometimes, when there is little or no expectoration, the bronchial respiration and bronchophony continue in this stage.

The physical signs of abscess and gangrene sufficiently explain themselves; they apply only to the cases where a cavity has been produced by the more or less perfect evacuation of the gangrenous or suppurated parts; and are, first, the coarse bubbling rhonchus, and afterwards, more rarely, the cavernous respiration and resonance, or pectoriloquy, which are described as the signs of tubercular cavities in phthisis. (See Tubercular Phthisis.) In the uncommon case of a large abscess, there may be the metallic tinkling instead of these signs. In the work formerly quoted will be found the only explanation that has been given of this sign, and this explanation has enabled us to generalize with success on the cases of its production, but it has too little connection with our present subject to require an exposition here. (Rational Exposition, &c., p. 136.) If the abscess or the sloughy portion of the lung has not been evacuated, auscultation teaches us nothing of the presence of either. Fetidity of the breath, especially in coughing, and of the expectoration, is the only physical sign of gangrene of the lungs. This may occur, however, in simple bronchitis, and it is only where auscultation has detected signs of pneumonia that it can be admitted as a proof of the death of a portion of the pulmonary tissue.

We have hitherto considered the general type of the physical signs of pneumonia in its most simple state, and we need say little on the varieties contingent on the situation or extent that the disease occupies. If it be confined to the central part of the lung, the spongy tissue of the surface may prevent the various sounds generated in the inflamed portion from reaching the ear; and this, we apprehend, happens far more frequently to auscultators in general than it did to Laennec, who states that he only met with one case of pneumonia where the stethoscopic signs were wanting; that he could detect a central spot of inflammation, not exceeding the size of a filbert, by the distant deep-seated crepitation, or bronchial respiration, heard beyond the pure murmur of the surface. It requires a very fine ear and considerable experience in auscultation to discover these signs at all in many cases of central pneumonia; and we believe, with Dr. Forbes, who made a similar comment, that it is expecting too much of auscultation to suppose it infallible in detecting every degree of pulmonary disease.

It has always appeared to us, that the more the student in auscultation holds in view the pathological state on which the signs depend, rather than

those signs themselves, and habitually reflects on their physical mechanism, as far as it is known, without empirically dwelling on names or bare descriptions of sound, the more surely will he estimate the value of this method of diagnosis, and the more instruction will he receive from it. He will thus see that central peripneumony may be so situated as to yield sometimes no physical symptom, and at others those to be discovered only by a very careful examination; and hence he will see the impropriety of a partial method of diagnosis, and the great importance of attending to the sputa and other indications. When the inflammation is extensive, all these difficulties vanish, and the more intense and puerile respiration in the sound portions of the lung, depending on the more rapid and forcible passage of air in them, further shows the infringement that has been made on the proper function of the organ.

It is not uncommon, especially in partial peripneumony, to observe the signs of the several stages of inflammation co-existent in different parts of the lung. Generally, the base or lower lobe, the part most liable to inflammation, presents its greatest degree, being hepatized, and yielding no sound of respiration or resonance on percussion; a little higher are heard the bronchial respiration and resonance, and above that the crepitant rhonchus, which mixes with and gradually gives place to the puerile respiration which occupies the upper parts of the lung. More rarely this order is reversed, the upper parts being the first and most affected. Bronchial respiration is particularly obvious when the hepatization affects the root or middle portions, without extending to the margins of the lobes; and the obvious reason of this is that there is still a passage of air through them to the sound parts.

The resolution or cure of peripneumony is marked by the reappearance, in a reversed order, of the signs which attended its progress. If the inflammation has reached only the first stage, engorgement, the resolution announces itself by the return of the respiratory sound, mixed with the crepitant rhonchus which before prevailed, and this pure vesicular murmur increases, whilst the crepitation diminishes, as the tissue becomes more free to the passage of the air. If the disease has proceeded to hepatization, the same recurrence of symptoms is observed; thus, in a spot where no sound of the ingress and egress of air had been heard, or perhaps only a bronchial respiration, a slight crepitation begins to be distinguished at the end of each inspiration, apparently produced by the air once more gaining admission through some of the fine bronchial tubes, whose calibres have been partially restored by the reabsorption of matter effused in and around their parietes. This sign, the *rhonchus crepitans redux* of Laennec, increases in intensity as the resolution proceeds; the bronchophony and bronchial respiration are diminished as the lung reacquires its spongy texture, and becomes a worse conductor of sound: after a while the natural respiratory murmur is heard mixed with the crepitant rhonchus, and as the texture becomes more permeable to the air, this increases as that diminishes, and the healthy state of the lung is thus gradually restored. It must be remarked, however, that this returning rhonchus differs slightly in character from that of incipient pneumonia, in its being less even in its crepitations; and as it increases in intensity, it gives more the sound of bubbles, resembling the mucous rhonchus, with which at this period it often becomes obviously mixed. The nature of the expectoration in retroceding pneumonia explains this difference, for we see in its diminished tenacity and more bronchitic character the reason why the crepitation ceases to be dry; and after a while, when their proper calibres are restored to the tubes and cells, the continuance of this secretion produces a simple mucous or bubbling rhonchus. We commonly, however, hear some crepitation in a part which has been inflamed, for some time after the resolution has apparently taken place; and this seems to indicate an œdematous state of the part, which we know in other instances to succeed to inflammation. If the inflammation has been of long continuance, especially if hepatization has existed for some time, the returning rhonchus is less regularly crepitant in its character; and if there be bronchial respiration present, this, instead of becoming diminished, is sometimes in a measure increased at first by the resolution. This fact, which has been also remarked by Drs. Graves and Stokes, (Dublin Hosp. Rep. vol. v.) seems to depend on the increased passage of air attending the reopening of the hepatized tissue before this has lost its good conducting power. The progressive change which supervenes, however, soon disguises this sound, not only by the tissue again becoming a bad conductor of sounds, but also by the bubbling or mucous rhonchus which generally occurs in a greater or less degree in the tubes which were before the seat of bronchial respiration. This change, compared with the free expectoration which commonly attends the resolution of pneumonia, exhibits a direct evidence of the interesting manner in which nature clears away effused matter from a tissue by free secretion from the adjacent membranes. When the hepatization has continued stationary for many days, the returning crepitant rhonchus is never so regular in its character as in more recent cases; and whilst in some points this rhonchus has appeared and already given place to one of a mucous kind, in others there is only a faint crepitation indicating a remarkable inequality in the progress of the resolution; some of these we should be disposed to view as cases of lobular pneumonia, in which the inflammation had commenced at several distinct points simultaneously; but in referring to the anatomical characters of the resolution of peripneumony before described, it will be seen that the restoration of the tissue to the healthy state is there seen to be also irregular and unequal, being probably modified by the degree of inflammatory orgasm in the different periods rather than by its absolute duration.

It is less easy to define whether any peculiar sign marks the restoration from the third stage, since we have no certain mark of the supervention of this stage. The coarse mucous rhonchus, which in fatal cases goes on increasing until it becomes tracheal and terminates the existence of the patient, in favourable cases becomes finer and less bubbling, in consequence of the free expec-

toration of the matter; and as this is secreted and cleared away, the air finds its entrance into the smaller bronchi and vesicles with a mixture of the mucous and crepitant rhonchi; these, in process of time, again yield to the natural vesicular respiration; but as may be expected from the degree to which the disease has attained, this restoration is very slow, and a subcrepitant rhonchus, depending on an œdematous state of the parts, often lingers for weeks after the other signs seem to indicate a removal of the peripneumony. The process of cure, after the formation of abscess, consists in the evacuation of its contents and its subsequent cicatrization. The signs of a cavity, the gurgling or cavernous rhonchus, or respiration, or pectoriloquy, therefore, gradually diminish until they nearly cease altogether; but there is generally left some dulness of the respiratory sound and of the resonance or percussion in the spot, often accompanied with a bronchial resonance, after the signs of cicatrization have appeared to be complete; and this is a natural consequence of the permanent modification which the disorganization has produced in the texture of the part. Laennec states that in several instances of abscess from partial peripneumony, which he observed in 1823, the cicatrization was completed within a period of from fifteen to forty days. In another patient who had pectoriloquy and cavernous rhonchus, over a space of three square inches on the lower part of the right lung, three months elapsed before these signs completely disappeared; and in another case, where a much smaller abscess existed in the top of the left lung, they did not entirely disappear until after six months; long before this, however, both these patients had recovered their flesh and strength, and considered themselves completely cured. In the few instances in which gangrene of the lungs has terminated favourably, similar symptoms have been observed; in fact, after the removal of the gangrenous portion, a cavity is left, which must be cicatrized precisely as that produced by an abscess.

Physical Signs of Pleuro-Pneumonia.—The extension of the inflammation of the lung to the pleura, (an event, as we have seen by the anatomical history, very common in pneumonia,) sometimes adds to the physical signs of the latter disease others of a novel character, which it is of importance to record. They depend exclusively on the presence of a liquid effusion, for as far as we have observed, we have been unable to recognise the affection of the pleura by physical signs, unless where this effusion has taken place. Some recent writers have indeed asserted that a creaking sound of friction is produced when the pleuræ are coated with freshly effused lymph, but this statement we have been unable to verify. The liquid effusion of a pleuro-pneumonia may declare its presence by producing of itself new physical signs, and by modifying those of the inflammation of the lung. Where the pleuritic effusion is not extensive, which is the common case, there may be so little liquid effusion that its presence can scarcely be detected, or it is discovered only by the greater deficiency of sound on percussion in the most dependent parts of the thorax, which parts regain a portion of their natural resonance when a change of posture raises them higher in relative position. Together with such a degree of effusion all the ordinary signs of pneumonia may present themselves without perceptible modification. But if the liquid effusion be greater, and sufficient to cover a considerable portion of the lung, it will disguise these signs, by rendering the crepitant rhonchus less distinct, while the sound on percussion is quite dull wherever the liquid reaches. If the pneumonia have attained the state of hepatization with bronchophony, and the point presenting this phenomenon be covered with liquid, the tone of the local resonance will become changed,—it will assume a cracked or bleating character, or rather a sound of this description will accompany the bronchophonic resonance. This combination of ægophony and bronchophony Laennec compared to the squeaking voice of punchinello; but besides the buzzing and squeaking combination of noises which this comparison represents, there is a tremulous or vibratory character in this morbid sound which seems alternately to approach and recede from the ear in sudden jerks. We have heard the voice otherwise modified by this combination of disease, as if it came through little cracked brazen trumpets; but, as far as we have observed, it is the undulatory or tremulous character which most constantly depends on the presence of the liquid, and is therefore the surest indication of the existence of a pleurisy. The most common seat of this phenomenon is the same as that of bronchophony, in the interscapular regions, but it may extend, especially when the effusion is abundant, through the whole of the ægophonic region, that is, in a band about three inches broad running from below the inferior margins of the scapula, in the direction of the ribs, to the sternum. It is most purely ægophonic in the anterior regions, there being commonly a noisy bronchophony behind. (See Pleurisy.) We have yet supposed the effusion only extensive enough to push aside slightly the lung from its apposition to the walls of the chest, and the sounds of pulmonary respiration are still heard pretty distinctly, modified by the inflammation, in the first stage into the crepitant rhonchus, and afterwards into the bronchial respiration and resonance; but there are some cases which we have described anatomically, and in which a copious pleuritic effusion has suddenly increased during a pneumonia, and has compressed and pushed aside the lung in such a manner that the sound of respiration can only be heard in the form of a crepitant rhonchus towards the root of the lungs, that is, in the scapulary, axillary, and infra-clavicular regions. This is the form of disease which produces the state before described anatomically under the name of *carnification*, and the pneumonia may in most of these cases rather be considered as secondary in existence as well as importance, and it is sometimes confined to a few lobules; but Dr. Stack inclines to the opinion that even in these instances the pneumonia is primary. (Dublin Hosp. Reports, vol. iv.) The pathological as well as the anatomical characters of pleuro-pneumonia lead to the belief that where one inflammation has greatly the predominance, the other is of trifling import, and that where both exist to a considerable extent, the complication, instead of presenting a more

aggravated case, rather mitigates the severity of both diseases, and this from a cause purely mechanical. The pressure exerted by the pleuritic effusion moderates the inflammatory action of the lung; and, again, the lung, in some degree consolidated by the inflammatory process, and not yielding to the encroaching effusion, sets limits to its accumulation. If, however, the intensity of a pneumonia is diminished by a coexistent pleurisy, its duration is probably prolonged; for the process of resolution is always much slower in this than in the simple case. This is because the interstitial effusion is more solid, and less mixed with the serous exhalation produced by common inflammation, and which cannot but assist in the discussion of the denser products. On the other hand, a pleurisy coinciding with a pneumonia will be of easier and speedier cure, inasmuch as the effusion is less abundant. The dry state of the carnified lung, taken together with the still constant production of the crepitant rhonchus in the course of the inflammation thus modified, affords an additional proof that this sign owes its existence to interstitial pressure *on*, rather than to any liquid effusion *within*, the air-cells.

Pathology of the general symptoms of Pneumonia.—Having made ourselves acquainted with the essential pathology of this disease, we may with advantage review the general symptoms in relation to it; we shall thus complete the circle of its history, and appreciate duly the value and importance of the various signs and symptoms.

In idiopathic pneumonia, arising directly from the application of an exciting cause, the inflammation commences before the febrile process begins; hence, during the period of general uneasiness, languor or depression, which are sometimes felt before an attack of pneumonia, the auscultator will generally discover a crepitant rhonchus in some part of the chest; sometimes there is a sense of fulness, soreness, or oppression about this part, or a stitch in the side; but these are often wanting until the supervention of fever, which first disguises, then develops the various general symptoms. At this time the pulse is commonly small, occasionally not altered in frequency, but generally accelerated. This is the latent stage of the inflammation, in which we cannot but point out its resemblance to the first effects of various mechanical injuries on a part of the body, which we have already shown to be produced according to a general law in the system. (See Irritation.) A cause has here been applied which has destroyed the balance of the circulation, and so affected the vessels of the lungs that their tonic power has suffered, and they become the seat of a congestive load of blood. This is the local injury, and first exerts its noxious or depressing influence on the system precisely as a crushed limb or a severe contusion would do, the local symptoms being more apparent in these latter instances because the animal sensibility of these parts is greater than that of the lungs. Hence the first symptoms of this, as well as of other inflammations, may be those of prostration or irregular reaction; and accordingly we find syncope, pallidity of the surface, vomiting, hiccup, &c., occasionally to precede the febrile stage of pneumonia. Rigor is, however, the more common symptom of commencing reaction, and it is the harbinger of that series of vascular movements which constitute the general and local character of phlegmasial pyrexia. After the rigor, which is accompanied by its usual smallness and frequency of the pulse, contracted coldness of the surface, and general depression of the powers, soon succeeds an increased action of the heart and arteries, indicated by a pulse of greater force and fulness, with more or less of the hard and sharp character of sthenic irritation; the surface becomes flushed and hot; and all the internal organs, the mucous surfaces, and secreting glands suffer from the febrile reaction in the interruption or perversion of their various offices. Under this influence the tendency of particular constitutions, or the morbid disposition of individual organs is discovered. In some the gastro-enteric mucous membrane especially feels the effect of this vascular excitement, and we have great thirst, scanty and high-coloured urine, tenderness of the epigastrium, irritability of the stomach, with a reddened tongue and fauces, and the various sympathetic signs of gastric fever. In another the fever assumes more of the bilious character, with bilious vomiting, turbid, saffron-coloured, and ammoniacal urine, and occasionally a jaundiced tinge of the skin. It is a rarer case for the head to suffer, but cases are not wanting in which great intolerance of light and sound, with delirium, have accompanied the symptomatic fever of pneumonia. In others, especially those of a plethoric habit, the fever is congestive; and besides the accumulation of blood in the focus of inflammation, there are other local determinations caused by the general vascular excitement; hence the head, the liver, the stomach, and the bowels may suffer, at once or singly, from the irritation extending its influence to a whole system of loaded vessels. It is during the development of this general reaction, which may thus vary in kind as well as in degree in different subjects, that the local symptoms declare themselves in the most prominent manner. Thus the same point of inflammatory congestion, with its crepitant rhonchus, which was perhaps the only local indication of disease, now increased and developed by reaction into active inflammation, becomes the cause of cough, pain, and dyspnœa in the various degrees that accompany the increasing period of pneumonia. It is not easy to define the cause of the variety in these symptoms which different cases exhibit;—why some patients should suffer scarcely any cough, while others are greatly harassed by it; why the breathing may in some be accelerated to a great degree without the patient being sensible of it, while others complain much of oppression when there is but a moderate encroachment on the function; and why some suffer acute and distressing pain, while others are scarcely conscious of any uneasiness. In a general way we must refer these differences to the state of the nervous system, the sensibility of which in these varying instances is sometimes exalted and sometimes depressed, either by individual peculiarity, or by some complication which the accompanying fever may produce. Thus, when there is a congested state of the vessels of the brain, sensibility is blunted, and the patient approaches the verge of suffocation without com-

plaining of either dyspnœa or pain. When, on the other hand, the inflammation is more concentrated within the chest, leaving comparatively free the sensorial functions, the exalted sensibility depending on inflammation is more easily felt, and this more especially when a part liable to tension, as the pleura, is involved in the disease. The urgency of the cough may also in a measure depend on the degree in which the bronchial lining membrane is inflamed; for if it is not affected, its sensibility will probably, through derivation, become lower than usual. Cough is occasioned by affections of the larger order of bronchial ramifications more powerfully than by those of the vesicular structure; and there is often, therefore, little of this symptom until the inflammation is extended to the lining of these tubes. From the absence also of the bronchial inflammation, there is often no expectoration at this early period; and cases occasionally present themselves in which it does not occur throughout the disease. The pathology of the secretion of the bronchial membrane, those viscid rusty sputa that so signally characterize peripneumony, is interesting. As in simple acute bronchitis this secretion becomes more tenacious in proportion to the intensity of the inflammation, so in this secondary bronchitis, when the vascular action of the membrane is augmented to its greatest degree, being as it were backed by the inflammation of the adjoining important and extensive vascular plexus, the secretion acquires still greater viscidity, and, in addition to this, becomes tinged by colouring matter from the mass of surrounding blood. When it is considered that this secretion proceeds from the immediate vicinity of the diseased part, it would appear that it must tend to relieve the inflamed vessels, and the inflammation, when very slight, may be terminated through this relief; but in the greater number of instances the relief thus afforded is too trifling to arrest the inflammation, and the viscid secretion, by still further obstructing the tubes and aggravating the dyspnœa, augments the danger of the disease, and this it does the more in proportion as its tenacity is greater.

The obstruction which the inflammation thus causes to the functions of pulmonary circulation and oxygenation of the blood now reacts in a new way on the circulating powers; the pulse, which at the commencement of the pyrexia had shown the heart to be vigorously contributing to the reaction, now falls in strength and hardness, whilst it commonly increases in frequency; and the stethoscope often discovers that there is a spasmodic briskness in the heart's contraction which seems to struggle vainly against the obstacle. Frequently this irritable contraction of the heart amounts to palpitation; and when we consider how its compartments must suffer from the injured balance of the circulation, this irregular action is readily explained. Owing to the obstruction in the lungs, the right side of the heart is unduly charged with blood, and subjected to the stimulus of over-distension; while the same obstruction prevents the left side from receiving its proper supply, and that blood which it does receive is but imperfectly arterialized. This pathological view, which is nothing more than a statement of observed phenomena, explains equally the violence and intensity of the inflammation in the pulmonary vessels, which are under the immediate influence of an over-stimulated right ventricle, and the weakness and failure of the general circulation, which depends for its support on the left ventricle. The depression thus occasioned by the failure of the general circulation, and by the imperfect oxygenation of the blood, is sometimes so great as to resemble typhous fever, whence such forms of the disease have obtained the name of *pneumonia typhodes*. Dr. Mackintosh has stated his opinion, in which we partly concur, that these varieties depend on the extent of the inflammation and obstruction to the pulmonary function, or on a complication with local congestions, and not on any thing specific in the pneumonia itself. The same writer thus expresses himself: "There is undoubtedly such a form of pneumonia, but I object to the adjunct *typhodes*, as expressing erroneous ideas of the pathological condition of the body. This form of pneumonia was very prevalent during the war, among troops stationed in exposed situations along the coast, and in large garrisons where the duty was severe. The soldiers were often seized with it when exposed at night as sentinels; instead of walking about, they frequently stand shivering in their sentry-boxes, the surface continues long chilled, and, with a view to fortify themselves and to produce warmth, they are in the habit of drinking ardent spirits in considerable quantity. In the strongest subjects I have seen the disease under such circumstances ran its course to a fatal termination in from forty-eight to sixty hours." (Elements of Pathology, &c.; 2d edit. vol. i. p. 420.) This sketch is well worthy of notice, as it illustrates the powerful effect in aggravating the disease, of two causes already noticed — long-continued cold and intoxicating liquors.

There is another complication of pneumonia which is very apt to give it an uncommonly depressed or typhoid type; this is, with severe bronchial affections, whether of the acute inflammatory character or of the asthenic kind, which goes under the name of peripneumonia notha. We have elsewhere described the peculiar prostration accompanying advanced states of these diseases, and have there referred this feature to the circulation of an imperfectly arterialized blood in the system, (see Bronchitis;) and we can readily conceive how serious such a complication must be in pneumonia. In persons advanced in life, and in frames debilitated by excesses or by a cachectic habit, the pneumonic inflammation is often accompanied by an early sinking of the powers; such individuals, after a few hours only of pain, cough, or acute symptoms, become lethargic or insensible, with a weak intermitting thready pulse, pallid skin, partial sweats, cold extremities, and, after lying in that state for some days, sink often without any of the prominent general symptoms of diseases of the lungs. This is a latent form of pneumonia which is far from uncommon; and although after death a large portion of the lung may be found in the second or third stages, none but a very attentive examination could have detected from the general symptoms the real situation of the fatal disease. Auscultation would have indeed furnished a much readier means of

discovering such an extensive organic lesion; but we have known cases to have deceived practitioners, competent and versed in the use of this method of exploration, from the circumstance that their attention had not been drawn to the thoracic viscera, all prominent symptoms having ceased before they had an opportunity of seeing the patient. In these and other latent forms of peripneumony, to which we shall presently revert, although no obvious dyspnœa be present, the frequency of the respirations may be detected on a close inspection, and the hand placed on the chest will often perceive the vibration of a liquid gurgling in the bronchi; these circumstances may lead to a suspicion of the existence of the disease, but it can be recognised with certainty only by auscultation and percussion: it is unnecessary here to detail this class of signs, as their distinctive characters will again come before us under the head of *diagnosis*.

[Typhoid pneumonia is exceedingly common in the eleemosynary institutions of many parts of the United States; and is often an intercurrent affection. It is apt to be mistaken or overlooked unless the physician is well aware of the physical as well as of the general signs.]

In its simpler forms, when the disease is extensive and has reached the second and third stages, the whole symptoms commonly show an abatement of the pain, fever, and other indications of exalted organic and animal sensibility, whilst there is an increasing injury and embarrassment of the function of the affected organ. The orgasm of the inflammation has in a measure expended itself in the effusion, and the general pyrexia sinks under the depressing influences of an injured function, with which the whole frame sympathises. This change in the character of the symptoms is of the highest practical importance, as it is a signal to modify the treatment in a material degree. The discontinuance of the more intense degree of inflammatory action is moreover evinced by the expectoration, which, losing its extreme viscidity and sanguinolent tinge, now bears more the character of a serous exhalation, or of a disordered mucous profluvium. The purulent and albuminous matter and bloody streaks that are sometimes seen in the advanced stages of pneumonia, are rather to be ascribed to the accompanying bronchitis than to the breaking down of the tissue of the lung: when the latter does happen, in the much rarer cases of abscess or gangrene, the expectoration is commonly very copious, that from an abscess being distinctly puriform, whilst that from gangrene contains pus, or mucus with a dirty brownish or greenish sanies, occasionally with portions of sloughy tissue, all characterized by an intolerable putrid fetor. The suppression of the expectoration which commonly occurs in fatal cases arises usually from the failure of the respiratory forces to effect its expulsion, and not from a cessation of the secretion. Hence by auscultation we hear a mucous or bubbling rhonchus, which goes on increasing and extending to the larger bronchial tubes, until it becomes tracheal, when it is audible to the by-standers, and constitutes the *death-rattle*, long known as a harbinger of death. Expectoration, as we have elsewhere shown, (see Expectoration,) so far depends on a free exercise of the organs of respiration, that unless air is carried beyond the accumulated matter, the expulsion of this matter can scarcely be effected. The short gasping breath drawn when a large portion of the pulmonary tissue is hepatized cannot accomplish this: the cough, when present, can scarcely reach the obstructing matter, and not unfrequently the sympathetic sensibilities and muscular powers on which this forcible respiratory act depends, are so much reduced that it ceases altogether.

In reviewing the symptoms of a favourable termination of pneumonia, the first class of phenomena which claim our attention are the critical evacuations. These, together with the preference which they show for particular days, are among the obscure laws which govern the human frame, and which must be the subject of far more extended observation before we can hope to explain them by reference to any of the simpler vital or physical influences. When Broussais ascribes critical evacuations to a predominance of a secondary irritation in a secreting organ over the primary, he only substitutes a new and unsatisfactory form of words for a simple declaration of the fact; for the salutary effect of the evacuation is much more explicable than the cause which determines its presence and its kind. Besides, the word irritation seems not a very appropriate one to apply to the influence which changes the skin from hot, harsh, and dry, to soft and perspiring, the urine from scanty, high-coloured, and scalding, to copious and less acrid, and the expectoration from very viscid and sanguinolent to an abundant, simple, and more liquid mucus. For the present we would prefer viewing critical evacuations rather as signs than as causes of improvement; for although in a free expectoration or a hemorrhage we can at once perceive a rational mode of relief, yet the cases of perspiration, diarrhœa, or a lateritious deposit in the urine, may with equal reason be viewed as a *consequence* of the diminution of the disease, which restores to the skin, the bowels, or the kidneys, such functional powers as enable them to carry off from the system matters accumulated during a period when the powers were more or less paralyzed or perverted by the general febrile derangement; and the fact that such evacuations do sometimes take place without proving critical is another reason for leaning to this view. The subject involves more conjecture than would be consistent with the design of a practical work, and we therefore abstain from entertaining it further than to remark, that no close observer of nature can refrain from the conclusion that, in one way or another, primarily or secondarily, a disordered state of the fluids forms an important link in all extensive febrile and inflammatory diseases.

The tendency to evening exacerbation in this and in other diseases is another phenomenon more observed than explained. We remember to have heard M. Andral cite in his lectures the personal experiments of a physician, which illustrated forcibly the effect of periodic habit on the body: for several nights in succession during the winter, at a particular hour, he plunged into a river, returning immediately to his bed. On intermitting the practice on certain days, a shivering

fit came on at the customary plunging hour, and was followed by the usual reaction, as if the plunge had not been omitted. Perhaps the evening exacerbations of this and other inflammatory and febrile diseases may be partly referred to the same law of habit, of which this is merely a prominent illustration. The addition of nutrient matter to the blood, together with the accumulated excitements of the day, produce a tendency to a febrile movement in the evening, and these causes are so regularly applied that their effect becomes a habit, and persists even when they are removed. With a few, the morning is the time of exacerbation, and with such persons this may be determined by a slight habitual disturbance, which is common at that period in dyspeptic individuals.

The rapid general improvement which commonly attends the progress of recoveries from pneumonia indicates rather the restoration of the healthy balance of functions than the entire removal of all local disease; for some dyspnœa and quickness of pulse often remain up to an advanced period of convalescence, and by means of auscultation we discover a cause in the still diseased state of portions of the pulmonary tissue. A bronchial respiration, a resonance of the voice, or a crepitant rhonchus, with some dulness on percussion, remains as a proof that the effects of inflammation are still present, and, amidst other signs of apparent recovery, these require time and care to secure their restoration. Sometimes, as we have seen anatomically, points of hepatization remain for a considerable time, and may become a focus for the rekindling of the acute disease by any error of diet or regimen; or, if left unsubdued, the inflammation may continue there in a chronic form. It is a commoner case that a crepitating or rather subcrepitant rhonchus persists; this, if there is no lingering fever or considerable cough, and if the expectoration has lost its red or yellow tinge and viscidity, is to be considered as the effect of œdema rather than of inflammation of the tissue, and is removed most effectually by a mild tonic combined with expectorants and diuretics.

Pathological Varieties and Complications of Pneumonia.—We have already noticed the complication of pneumonia with bronchitis, and the effect that it commonly has of increasing the depression attendant on the disease, and thereby disguising its inflammatory nature. Drs. Graves and Stokes (Dublin Hosp. Rep. vol. v.) have judiciously remarked that in the treatment of this combination the first remedies and a single bleeding produce such relief to the bronchitis, that a practitioner may be led to suppose that the whole disease is overcome; whereas auscultation discovers, by a remaining crepitant rhonchus, that the most formidable affection still remains to be subdued. There are, however, a few instances in which this combination puzzles even the auscultator. The pneumatic crepitation is sometimes so masked by a loud and general mucous rhonchus that even an attentive examination may fail to detect it: this happens especially when the pneumonia is central and towards the root of the lungs, and does not extend to the surface. Laennec indeed asserts that a deep-seated crepitant rhonchus can always be distinguished, by those practised in the stethoscope, from any mixture of sounds produced nearer to the surface; but we now think that to insist, as we once did, on the possibility of this distinction, would be to reckon too much on the infallibility of auscultation. The presence of a rusty tinge in portions of the expectoration will more frequently declare a latent peripneumony; and in the progress of the disease the extension of the inflammation to the surface will make it more easy of recognition. Pneumonia may arise in the course of either acute or chronic bronchitis, and such an event is of great importance in both cases. Acute bronchitis is most liable to pass into peripneumony in young subjects; and the habitual chronic catarrh of old people sometimes takes a similar course. Andral remarks that this accident is not an unfrequent cause of the kindling up of fever and increase of dyspnœa in aged asthmatic subjects; and these symptoms may erroneously be ascribed to an aggravation of the habitual senile disease; this increases the danger of the complication, and for causes that we have just explained, the diagnosis must often rest on uncertain general symptoms.

There are two modifications of bronchial inflammation which occasionally exhibit a strong tendency to pass into pneumonia, pertussis and the influenza or epidemic catarrh. The violent fits of coughing frequently coexisting in these complaints with considerable fever, appear to us to have a great share in extending the inflammation to the great pulmonary plexus of vessels. These paroxysms of cough determine a great degree of congestion in the lung, and we have already seen how easily such a congestion may become inflammation. Of such a termination of hooping-cough we have witnessed numerous instances, proved in some by anatomical inspection, and in many by the addition of a crepitant rhonchus to the physical signs of pertussis. In many of the latter cases the fever had been so gradually increased, and the general peripneumonic symptoms had been so mixed up with those of the aggravated pertussis, that but for auscultation the more serious disease might have escaped detection. This complication is most common in very young and delicate children, and during winter and spring, the usual peripneumonic season. Of the supervention of pneumonia on influenza we have seen several instances during the epidemic that has lately prevailed to so great an extent, and from the effects of which the country is still suffering (May, 1833). It was at the time of its greatest prevalence, when the weather was cold and changeable, that the disease in occasional examples put on this decidedly inflammatory type. In two instances we resorted to free bloodletting with immediate relief; and it is worthy of remark, that the patients suffered less from weakness than many others where no depletory measures were adopted.

[In children especially, in whom no information from the sputa is attainable, bronchitis often masks pneumonia. In them, too, the sounds afforded on percussion may be alike on both sides, as the affection is rarely confined to one lung. Previous to six years of age, the symptoms and progress of the disease differ somewhat from those of a later period. It would seem, according to Messrs. Gerhard, Rufz, and Rilliet and Barthez, to occu-

then as a secondary lesion; and it has been conceived to be owing to a stagnation of blood in the lungs, which acts as a foreign body as it were, and concurs in producing an alteration in the pulmonary tissue with which it combines, and becomes identified, so as to form hepatization of the lungs. Although, however, in very many children, the disease is generally secondary, in other cases it attacks those in perfect health, and runs its course in a brief space of time,—occasionally in forty-eight hours. Howsoever this may be, it is certain, that in younger children, the diagnosis between pneumonia and bronchitis is not easy.]

We have before described the combination of pleurisy with pneumonia. Next to bronchitis, it may be said to be the most natural concomitant of the parenchymatous inflammation, for its contiguity exposes it to be involved in an extension of the disease. As we have said before, it may considerably modify its course, but instead of, as bronchitis, disguising the seat of the complaint, it often declares it more openly by adding the prominent symptoms of pain or stitch in the side, and a catch in the breathing. These obvious symptoms are not, however, the constant concomitants of pleuro-pneumonia; and cases sometimes present themselves in which this and every other variety of the disease require the fullest investigation of both physical and general signs to ascertain their nature with precision. As far as we have observed, a pleurisy supervening on pneumonia aggravates the case most when it is attended with a sharp pain and catch in the breathing; for it then keeps the patient in a distressing struggle between pain and suffocation, and unless the pain yield soon, it may in this way prove fatal. Generally it soon subsides, the active orgasm being derived to the pulmonary tissue, which on account of its greater vascularity is more obnoxious than the pleura to the inflammation. For this reason it is not common for the pleurisy to gain on the pneumonia, and it is usually limited to the points where the latter reaches the surface.

[It is maintained by some pathologists, as by M. Valleix and Dr. Gerhard, (*Lectures on the Diseases of the Chest*, p. 88, Philad. 1842,) that inflammation of the pleura rarely complicates the pneumonia of children. By others, however, the complication has been found to be common, the pleura being unaffected in the observations of MM. Rilliet and Barthez, (*Op. cit.*) in ten cases only. Evidences of acute pleurisy existed in one third of the children from two to five years of age.]

Peripneumony frequently attacks phthisical subjects in both the early and the advanced stages of tubercular disease. Miliary tubercles in the lungs may be viewed as causes both predisposing and exciting; they render persons more liable to inflammation on exposure to cold or any other exciting cause; and during a febrile state of the system, their presence and mechanical irritation may localise in this organ a general inflammatory diathesis. In several instances of subjects who have died of continued fever with pneumonia, we have seen numerous tubercles in the inflamed lung, and similar cases are recorded by Andral and others. The liability of phthisical subjects to intercurrent peripneumony has been noticed by Laennec, Louis, and Andral. It is not generally severe, and is often spontaneously cured; which illustrates a remark which we have before made, that pneumonia excited by a local cause is never so severe as that which arises from an extensive impression on the circulation. Nevertheless, the similarity of its symptoms to those of the phthisical disease often screens it from notice, with the effect that its treatment is neglected, and if it does not at present endanger life, it accelerates the progress of the other fatal disorder. Hence, as Laennec recommends, it is important to examine from time to time the chests of consumptive patients, particularly when there is any sudden feverish attack or decrease of the strength. Andral asserts that intercurrent peripneumony, from being overlooked, frequently occasions the death of phthisical subjects.

We have had occasion to speak of the occurrence of pneumonia in the course of various febrile disorders, and it is the more important, as the inflammation here commonly takes a latent form. This is especially the case in severe small-pox and erysipelas, and in fevers of the congestive kind. In a considerable proportion of the fatal cases of these diseases, this inflammation seems to be the cause of death. During the prevalence of a peripneumonic epidemic, and in the winter season, Laennec remarks that in patients suffering under these disorders, any marked increase of fever in the young and robust, and any sudden prostration of strength and loss of consciousness in the aged and debilitated, are generally the result of a pneumonia supervening, and it is frequently accompanied with neither dyspnœa, cough, expectoration, nor any of its usual symptoms. The frequent occurrence of a latent pneumonia in continued fever is a fact too well known to morbid anatomists; it has already been noticed in the article Fever continued. A harsh state of the skin, fetid excretions, and sordes on the teeth and tongue coming on in subjects worn out by cancer or other severe chronic diseases, according to Laennec, frequently indicate pneumonia, which soon ends with coma, tracheal rattle, and death. The bronchial affection of measles sometimes passes into pneumonia, especially if the eruption is repressed or disappears suddenly; but in this case the symptoms are commonly urgent and sufficiently characteristic. Endemic fevers sometimes determine an inflammation of the lungs, which is frequently latent. Broussais records this of the intermittent fevers which attacked the military in the hospitals of Bruges. (Hist. des Phlegmasies Chron. t. i.) The same has been remarked of malaria fevers of other kinds, and of the pestilential cholera. The latter disease sometimes shows a remarkable tendency to pneumonia in the stage of reaction, and this event seems to be favoured by the great congestion which occurs in the pulmonary vessels during the period of collapse. The reaction of intermittent febrile diseases has been sometimes observed to be so regularly accompanied by pneumonic symptoms that some authors have given the name of intermittent peripneumony to these affections. Thus Broussais has noticed the quotidian returns of inflammation both of the lungs and of the

pleura at the time of the febrile paroxysm. But it must be remarked that in these cases either the pulmonary affection must have been exceedingly slight, or it must have continued during the apyrectic period, and merely have been more fully developed by the excitement of the paroxysm.

Pneumonia is sometimes produced in gouty and rheumatic subjects, and this may occur either vicariously, so that the limbs are relieved, or conjointly with the affections of these. In the first case, the pulmonary affection is generally apparent; in the latter, it is sometimes latent. P. Frank has remarked that in rheumatic subjects pneumonia sometimes terminates without any expectoration, with a copious discharge of clear urine, amounting to twelve pounds and upwards. This curious fact is another sign of the connection which subsists between rheumatic and gouty affections, and a diseased state of the fluids of the body.

Hypertrophy of the heart modifies the pulse in pneumonia in a manner that deserves notice. Instead of falling in strength as it generally does, and becoming small and frequent, from the causes that we have before explained, the pulse in some degree retains the hard vibrating character peculiar to hypertrophy. This is the case, however, only when the left ventricle is affected. Hypertrophy of the left ventricle predisposes to pneumonia, and generally aggravates its form. In pneumonia complicated with any disease of the heart, the pulse becomes more fallacious than ever; and neither its frequency nor its strength bears any relation to the extent of the inflammation.

Inflammation of the mucous membrane of the stomach and bowels is by no means an uncommon accompaniment of pneumonia. It generally gives a more adynamic type to the disease, and manifests itself by the peculiar state of the tongue, which is at first very red, and afterwards parched and brown, with great thirst, vitiated excretions, and frequently tenderness at the epigastrium. Various other diseases may combine themselves with pneumonia, and although they may manifest themselves by their peculiar groups of symptoms, yet the complication generally increases the obscurity of the case, and the difficulty of its treatment.

[In children, from the age of two to sixteen, there would appear to be six diseases in the course of which pneumonia is apt to occur in very large proportion. Thus, according to M. Grisolle, (*Op. cit.*) secondary pneumonia occurs in seven-eighths of all cases of cramp; in five-sixths of all cases of cancrum oris; in one-third of all cases of enteritis, measles, and hooping-cough; and in one-fourth of all cases of small-pox. According to the same observer, intercurrent pneumonia was seen in one-seventh of all cases of continued fever; one-sixth of all cases of acute affection of the brain; one-fourth of cases of pulmonary tubercles; one-fourth of cases of disease of the heart; and in about one-sixth or one-seventh of all cases of cancerous disease of the viscera; organic diseases of the liver—especially cirrhosis, Brights' disease, &c. It is likewise a frequent complication of glanders, phlebitis, &c.]

Several surgical writers have noticed the occurrence of pneumonia after amputation and other great surgical operations, and likewise after extensive wounds; and it has been supposed that this disease is frequently the cause of death in these cases. This is a very interesting subject, and one that requires further investigation. The disease of the lungs in these instances appears to be quite of the latent kind, and sometimes it only declares itself by the dyspnœa and rattle a short time before death. We cannot speak from personal observation on this subject; but from the description given, it would seem that these cases of pneumonia may be ranged in two classes: those which partake of the character of the pneumonia of the moribund, which has often been alluded to in this article, and which seems to be a concomitant rather than a cause of the changes of death; and those which supervene during a febrile reaction, and are disguised by other local and general symptoms. The latter class occurs most commonly in the subjects of amputation, or where a great change has been wrought in some part of the circulation, leaving the heart vigorous and disposed to sthenic reaction. The former comprises cases of bad wounds or unfavourable operations, where the powers fail under the local injury, and as a part of this failure, a congestion takes place in the lungs, which is, by a partial reaction, converted into inflammation.

[From a table of forty-one deaths, following various injuries and diseases, in the surgical wards of University Hospital, London, — in which an account of the state of the lungs was kept,—these viscera, according to Mr. Erichsen, (*London Medical Gazette*, Feb. 1841,) were found in twenty-three cases to be in the first or second stages of pneumonia. On this account it has been suggested to defer operations, when practicable, during the prevalence of an epidemic pneumonia.]

It will be perceived that, in describing these various complications, we have comprehended nearly all the varieties of pneumonia which have been described by authors; and we apprehend that the pathological views of these varieties with which modern researches have so fully furnished us, so clearly expose the real nature of the greater number, that it is unnecessary to consider them further in a separate form. The false or bastard peripneumony, (*peripneumonia notha* of Sydenham,) does not require notice here, for it has been already described under its proper head, Bronchitis. The bilious peripneumonies described by Stoll and other writers of his time, do not appear to constitute a real pathological variety of the disease: for they were either cases of bronchitis in which the sputa were tinged with bile from a simultaneous affection of the liver; or, what is more probable, they were ordinary cases of pneumonia attended with the characteristic expectoration, which is often yellow or greenish, from the admixture of various proportions of the colouring matter of the blood, and which these writers hypothetically ascribed to an intermixture of bile. Laennec says that he has frequently met with these greenish sputa where there existed no bilious complication: he admits that he has sometimes seen them disappear after bilious evacuations; but

this circumstance can be viewed in no other light than that these evacuations were critical, and coincided with a resolution of the inflammation.

Diagnosis of Pneumonia. — We have devoted so much space to the consideration of the signs of this disease, that we have now only to recall the most characteristic, and compare with them the distinctive signs of a few other maladies with which they may be confounded.

The manner of attack, the dyspnœa, the pulse, the pain, the cough, and the side of the decubitus, although in the manner in which we have described them, they contribute to form the general character of the disease, yet are quite incompetent to distinguish it with certainty from other acute inflammations of the chest, particularly bronchitis and pleurisy. Still these symptoms are not to be disregarded, for, taken in conjunction with the physical signs, they often assist us much in the diagnosis. Of all the diagnostic signs of pneumonia, the characteristic form of the expectoration is the most infallible; and when it does occur, there can be no doubt of the existence of parenchymatous inflammation; but it is sometimes entirely absent; frequently it does not appear until after the disease has existed for two or three days, and it generally ceases as the inflammation reaches the second and third stages. It may moreover pass by such insensible gradations into the colourless form of bronchitic sputa, so that it is not always easy to determine whether it partakes of the pneumonic character or not. The crepitant rhonchus, when it occurs distinctly or unmixed, and in conjunction with the general signs of pneumonia, may be considered as quite pathognomonic; and as its presence is much more constant than that of the expectoration, it may be considered as the more available diagnostic sign. Laennec considered it the most important of all physical signs, "inasmuch as it is invariably present, and from the very invasion of the disease; and exists in no other case, except in œdema of the lungs and pulmonary apoplexy, two diseases which are easily distinguished from this by their own peculiar signs and symptoms. M. Andral is mistaken in saying that the crepitous rattle sometimes exists in acute bronchitis, (Clin. Méd. tom. 2. p. 333,) and I think this is evident from his own cases. From its constant presence in this disease, I regard it as the most practically useful of all the stethoscopic signs, inasmuch as it points out, in its very earliest stage, one of the most severe and most common diseases, and thereby enables the physician to apply his means with much more chance of success than he could have done even a few hours later." (Dr. Forbes's Transl. p. 213.) M. Piorry has lately questioned the pathognomonic relation of the crepitant rhonchus to pneumonia, not from observation of disease, but from the circumstance that a crepitation like it may be produced on applying the stethoscope to a lung out of the body. (Gazette des Hôpitaux, t. 6. No. 116.) Such an hypothetical objection cannot, however, be entertained, in opposition to the mass of evidence in corroboration of Laennec's opinion, and we have already explained how the artificial crepitation in question is produced. (See page 606.)

The preceding characters will be quite sufficient to distinguish recent pneumonia from pleurisy. In the latter the sound of respiration is unaccompanied with a rhonchus, and is only rendered weaker, first by the pain restraining the respiratory movements, and afterwards by the liquid effusion pushing aside the lung. There is sometimes dulness on percussion in the early stages of both diseases; but in pneumonia this dulness will be found to be fixed in the spot where the crepitant rhonchus is heard; in pleurisy, on the other hand, it generally occupies the most dependent part, and changes with a change of posture. This last criterion, which is very easily applied, is sufficient to discover moderate pleuritic effusions in every case except in that of the effusion being limited by adhesions of the lung to the ribs. This ægophonic resonance of the voice, when perfect, is another sign equally distinctive of pleurisy; but as for its production there must be only a certain thickness of the layer of fluid, its presence is often of short duration, and it may thus escape detection. The diagnosis between these diseases is much more difficult in their advanced stages, particularly when they are extensive. Thus it may happen that we are called to see a patient who has been ill for a considerable number of days, and who has had more or fewer of the equivocal general symptoms which are applicable to either pleurisy or pneumonia; by auscultation we find no sound of respiration in one side of the chest, which is also quite dull on percussion. The question then presents itself—is the case one of pneumonia, with the whole lung in a state of hepatization, or is it a case of pleurisy, acute or chronic, with a very extensive effusion? These difficulties have been sagaciously pointed out by Dr. Stack, (Dublin Hosp. Rep. vol. iv.) and we admit them to be sufficient to mislead any but a very careful observer. But an attentive consideration of the previous history, and a minute examination of the physical and some general signs, will, we believe, always furnish us with a correct diagnosis. We have in two instances been mistaken, but we refer our error rather to the insufficiency of our examination than to an absence of diagnostic signs; and these cases, which occurred in dispensary practice, presented a rare combination of deceptive circumstances. The most obvious distinction between a hepatized lung and copious pleuritic effusion is the constant occurrence, in the former case, of a loud and almost pectoriloquous bronchophony under the scapula, along the spine, and below the clavicle, and the general absence of this sign in the latter. This test would have been sufficient to distinguish the case cited by Dr. Stack as one of peculiar difficulty; the absence of this resonance clearly proving it to be pleurisy and not pneumonia. The *presence* of this bronchophony is not, however, an equally sure proof that the lung is hepatized. In one of the instances before alluded to, with a perfect deadness of sound on percussion over the whole of the right side of the chest, a bronchophony and bronchial respiration were heard between the scapula and spine and below the clavicle on this side, from which we too hastily concluded the disease to be pneumonia; on dissection it proved to be pleurisy, the right thorax being full of serum and lined with a dense

false membrane; the lung was compressed by the effusion into a mass which adhered by solid pillars to the upper part of the cavity under the clavicle and to the posterior part exactly in the points where the bronchophony had been heard. These adhesions were obviously the cause of the sign which misled us; and as the possibility of their occurrence in other cases must detract from the certainty of its indications, we must seek for further means of distinction. In copious pleuritic effusion there are commonly several signs of displacement, which are absent in hepatization of the lung. Thus the affected side is commonly enlarged, as can be ascertained both by inspection and admeasurement. By viewing or feeling both sides of the chest at the same time, if there is no obvious enlargement, it may be perceived that the affected side does not partake, equally with the sound side, of the respiratory movements; it remains stationary in a fixed state of distension, and this in a more remarkable degree than occurs with a hepatized lung. The intercostal spaces are also more prominent on the affected side, which gives it a more rounded appearance; this character readily distinguishes pleuritic effusions from hepatization in thin subjects, but it fails where the integuments are fat or œdematous. Dr. Stokes has pointed out some other means of distinction, founded on the same circumstance of displacement, which occurs exclusively in pleurisy. (Dublin Med. Journal, March, 1833.) If the disease occupy the left side, a copious pleuritic effusion will generally displace the heart, which will be heard and felt pulsating, not in its usual place, but to the right of the sternum; in pneumonia the pulsations are not displaced, but they are uncommonly audible throughout the affected side. If the disease be on the right side, an effusion will push down the liver, and make it perceptible below the false ribs; it will also press aside the sternal mediastinum, so that the whole sternum would sound dull on percussion; in hepatization of the whole right lung there is neither displacement of the liver nor of the mediastinum; and as the resonance of the sternum on percussion depends on portions of both lungs beneath, its right half would yield a dull and the left a clear sound. By some or other of these distinctive marks we may venture to assert that a pretty certain diagnosis between pneumonia and pleurisy may always be obtained. For further particulars on this point we refer to the articles Pleurisy and Empyema. The distinction of slight degrees of pleurisy accompanying pneumonic inflammation will depend on the circumstances that change of posture modifies the sound on percussion, rendering the dependent parts the least sonorous, and that the bronchophony is rendered bleating or vibratory whenever a thin stratum of liquid is interposed between the pleuræ. Pleurisies circumscribed by adhesions are scarcely to be recognised unless when sufficiently extensive to cause a fulness of the intercostal spaces. But as we have before remarked, the pleurisies supervening on pneumonia generally are of secondary importance, and their detection is not an object of great interest.

Bronchitis in its severer forms is frequently confounded with pneumonia; it is often by the physical signs only that they can be distinguished with certainty; and even these sometimes fail to detect a latent pneumonia in combination with bronchitis. In pure bronchitis no crepitant rhonchus occurs, but there may be a variety of mucous, sibilant and sonorous rhonchi. The distinction of these from the pure crepitation of peripneumony is sufficiently obvious, but it is not so easy to distinguish this crepitation when it is mixed up with the other rhonchi. In these difficult cases we must look more to the expectoration, progress of the symptoms, and state of the countenance. With respect to the latter indication, as a diagnostic mean in bronchitis, pleurisy, and pneumonia, we have received some valuable hints from Dr. Stack, (Dublin Hosp. Rep. vol. iv. p. 90, et seq.) although we can scarcely accede to his opinion that it is generally more sure than the physical signs. In pleurisy, either the face is flushed, and the lips are florid, or their appearance is not changed from that of health. In humid or severe bronchitis, the parts of the face usually coloured and the lips are more or less blue or livid, according to the extent of the bronchial membrane affected, and the quantity of secretion in them, which prevents the oxygenation of the blood. The flush of pneumonia is different from either, being an intermediate shade of purplish red. There is no correspondence between the flush often observed in one cheek and the side affected, and the flush often shifts from side to side. In pleurisy and bronchitis, the colour in the lips and cheeks is commonly circumscribed, the other parts being uncommonly pale; but in pneumonia the redness, when present, is more suffused over the whole countenance. These variations of colour, which seem to depend on the degree in which the functions of arterialization and circulation of the blood are respectively affected, may assist us in doubtful cases in forming a diagnosis, but we have seen them fail too often to place implicit reliance on them. In the advanced stages of pneumonia, bronchial resonance and respiration and the perfect dulness on percussion sufficiently distinguish it from bronchitis, in which the mucous rhonchus and a considerable clearness of sound on percussion persist until the last. Dr. Stack, indeed, cites a case of humid bronchitis, in which, a few hours before death, the chest yielded no resonance; but no such example has been elsewhere described, and the anomaly must be attributed to the moribund state of the patient, and the imperfect entrance of air into the lungs at that period.

The physical signs of extensive pulmonary apoplexy sometimes approach closely to those of peripneumony, there being in the spot affected a dulness of sound on percussion and absence of the respiratory murmur, surrounded by a crepitant rhonchus. The absence of fever, however, and the presence of hemoptysis will generally be sufficient to characterize the former disease; and, by referring to its history, it may be perceived that there is commonly much difference in the origin and progress of the two complaints. An inflammation of the tissue of the lung is sometimes engrafted on apoplexy of the organ, and it will then be more difficult to distinguish; but the access of feverish heat, the increase of the crept

tant rhonchus, and the viscidity of some portion of the sputa, will generally give evidence of the complication.

Combinations of several affections of the chest will sometimes, more closely than simple diseases, simulate pneumonia. Œdema of the lungs combined with pleurisy or even pleurodyne, may produce physical signs resembling the first stage of peripneumony, and a similarity in many of the general symptoms increases the difficulty of the diagnosis: the different character of the expectoration, and the history and progress of the case, are the means of distinction most to be relied on, and an attentive examination of these will seldom fail to lead to a correct decision. It is sometimes more difficult to distinguish between chronic induration of the lung, whether from chronic peripneumony, agglomerated tubercles, or melanose formations, and the hepatization of local acute inflammation supervening on phthisical disease. If the case has been watched, the attack of the latter affection must have been marked by some augmentation of the fever and dyspnœa, and the physical signs of the first stage would have further characterized it; but if the hepatization is complete before the first time of examination, we must remain for a time in doubt. These local hepatizations are sometimes formed and reabsorbed without much aid from treatment, and it is therefore less important to distinguish them than the inflammatory stage which precedes them, and which is, as we have just observed, cognizable by its peculiar signs.

In fine, we would recommend the student to found his diagnosis as much as possible on a knowledge of the true characters of disease, rather than to any detailed distinctions which can be comprised in a treatise. The varieties and complications of diseases are too numerous to be capable of adaptation to any fixed rules of diagnosis; but when the mind of the observer is fully imbued with the principles of a true pathology, his judgment will find in any combination of phenomena some means of distinction less fallible than the memory can ever furnish from the most minute exposition of possible cases.

Prognosis.—The remark which we have just made on the subject of diagnosis may with nearly equal force be applied to the prognosis, or estimate of the severity and probable issue of the disease. Our study of the pathology will lead us to form a correct opinion more surely than any enumeration of good or bad signs. The prognosis of this disease is always serious, and even in favourable cases must be spoken of with caution, for cases, which are slight at first, sometimes take an unfavourable turn; and in progress towards recovery, as long as the disease lasts, there is a chance of a relapse, which may throw the patient into new and peculiar danger. The circumstances of the pathology of a case which affect the prognosis, are the degree of the inflammation, its extent, its seat, its complication with other affections, and the condition of the various functions of the body.

[The average duration of pneumonia is from twelve to twenty-four days. At times it continues only two or three days; at others, it may go on for thirty or forty. Of 78 cases observed at the Hospital La Charité, Paris, between the years 1821 and 1827, twenty-eight, according to M. Louis, proved fatal.]

As is the case with other inflammations of important organs, the continuance of the disease increases its mischief and danger as it injures the organization of the part; hence the prognosis is more serious if hepatization has taken place, and still more so if the signs seem to indicate the supervention of the third stage. The duration of these stages varies very considerably according to the effect of the treatment and the age of the subject. Laennec states the average proportion to be as follows: "The obstruction, or first stage, usually lasts from twelve hours to three days before passing to the state of complete hepatization: this lasts from one to three days before spots of purulent infiltration make their appearance; and the period of suppuration (from the time when the concrete purulent infiltration is distinctly perceptible until this is completely softened into a viscid fluid) varies from two to six days. Bloodletting, derivatives, and resolvents or stimulants of the absorbent system, obviously retard the progress of the disease, and consequently prolong the period of the first two stages. Convalescence is rapid in proportion as the inflammation is of small extent and has been early checked." (Op. cit. p. 211.)

We have already had occasion to remark that in children the inflammation continues for a much longer period in the first stage; after some weeks' duration, presenting only some hepatized points at the margin of the lung or in isolated lobules. Laennec has observed the same peculiarity in certain epidemics, as in the *grippe* of 1803, when he noticed the first stage to continue for seven or eight days, sometimes affecting the whole of one lung, and part of the other, and proving fatal before any distinct hepatization occurred. We have before mentioned, on the other hand, the remarkable tendency of the inflammation in old and debilitated subjects to pass rapidly to the state of purulent infiltration; the author just named describes this to take place sometimes within thirty-six or even twenty-four hours. Recovery is sometimes affected by resolution and reabsorption from every degree of pneumonia, but the chances of this favourable termination are very small when the signs of hepatization have continued for such a length of time that purulent infiltration has probably occurred. Even simple hepatization requires time and favourable circumstances for its removal; for besides that the deposited matter obstructs the due function of the part, and thereby prevents the restoration of the balance of health, it likewise remains as an irritating cause, giving a proclivity to the recurrence or continuance of inflammatory action. Unless, therefore, the tendency to this be kept in a state of subjection, and the process of absorption be perceptibly gaining ground, the prognosis must continue to be doubtful. The supervention of gangrene will always increase greatly the danger of a case. If the gangrene is extensive, it must inevitably prove fatal; and where small and circumscribed, if the powers of the system are weak, they can scarcely be sufficient to support life until the noxious dead matter is thrown off; if, however, the pulse and muscular system show still considerable strength,

this process may be happily effected, and there are recorded instances of recovery even from the gangrenous termination of pulmonary inflammation. An interesting case of this kind recently fell under the observation of the writer in conjunction with Dr. Chambers and Mr. Jay of Sloane-street, and was watched with great interest during a doubtful period of several days; the inflammation in the second state affected the right lung, and signs of excavation (concluded to be gangrenous from the odour of the expectoration) were heard at the inferior angle of the scapula; the case was greatly aggravated by the sudden supervention of a pleurisy on the left side, excited probably by the irritation of gangrenous matter in the circulation. This new attack, and the depletions necessary to subdue it, greatly increased the danger; but the powers of life ultimately prevailed; the expectoration became less fetid, more purulent and abundant, and after some time gradually ceased under the influence of a mineral acid; the cavity progressively diminished was at length cicatrized, and the patient, in three weeks from his worst state, was quite convalescent.

The extent of the inflammation, as may be anticipated, greatly affects the danger of a case. A double pneumonia affecting both lungs at once is frequently fatal, even in the first stage; and whenever the whole of one lung is involved, there is much peril of an unfavourable issue. Cases do occur, however, although rarely, in which the gravity of the case does not bear proportion to the extent of the inflammation; and these anomalies in great measure depend on the natural capacity of the function of respiration in the individual, and its power to bear abridgment. Thus we sometimes see a pneumonia of small extent occasion orthopnœa and other symptoms of a severe case; whilst in another example auscultation may indicate that nearly a whole lung is involved, yet the patient is scarcely sensible of dyspnœa, and the other functions are not greatly disordered.

Inflammations attacking the superior lobes and root of the lungs are more fatal than those confined to the base or lower lobes; and this circumstance explains the discrepancy of authors, before noticed, respecting the comparative frequency of inflammation in these different parts. The cause of the difference appears to be, that disease of the upper portions and root of the lungs obstructs the passage of blood and of air in the larger vessels, so that the peripheral parts unaffected with inflammation do not receive their due supply.

The complication of pneumonia with other affections generally increases the danger of a case: thus peripneumonies supervening in the course of fevers and the exanthemata are generally of a serious nature; and the more formidable because they are often latent. Inflammatory affections of the gastro-intestinal canal, coinciding with pneumonia, render it less tractable and more dangerous; and the same may be said of bronchial, pericardial, meningeal, and peritoneal inflammations. Pleurisy, as we have seen, may diminish the intensity of the inflammation, if it is on the same side; but if it attacks the opposite cavity, it must aggravate the functional disorder. Pneumonia occurring in the course of phthisical disease is seldom severe in itself, but it has a tendency to accelerate the development and softening of the tubercles. This inflammation is more than usually fatal during pregnancy and in the puerperal state. It is especially dangerous at the extremes of life, more particularly in weakly infants and in cachectic old people, and those exhausted by habitual excesses; and the fatality is much greater among the lower classes than among those well and regularly fed and clothed. Mr. Chomel observes that the mortality in hospitals amounts to a fourth of the cases, which is considerably more than what occurs in private practice. The same physician gives the following statement respecting the influence of age in the mortality of pneumonia: in seventy-nine cases, of thirty-three at ages between 18 and 30 years, three died; of nine aged from 30 to 40, two died; of eleven aged from 40 to 50, five died; of fifteen aged from 50 to 60, eight died; of eight aged from 60 to 70, four died; and the three cases which occurred beyond the age of 70, all terminated fatally. (Dict. de Méd. t. xvii. p. 233.)

The state of the functions in pneumonia, although it is not sufficiently constant to be of much use in determining the diagnosis, is often an important guide to the prognosis of individual cases. Thus a severe degree of dyspnœa, when constant, increasing and unyielding to treatment, may justly excite our serious alarm; and the more so as it is conjoined with a state of the circulation which betokens a continued predominance of irritation, or a failure of functional strength. Thus, when in a case of severe dyspnœa the pulse is very quick, as above 120, without much strength, there may be reason to fear that the system may not bear the treatment necessary to arrest the course of the disease, and our opinion must be in a proportionate degree apprehensive: the knowledge, through the physical signs, that the inflammation in its second stage is the cause of this state of the symptoms, will diminish our hopes, as we know it to be then less within the power of medicine; and when the pulse becomes small, weak, and intermitting, the danger may be considered imminent. There may, however, be extensive and serious disease without exciting this combination of symptoms; and although their presence positively indicates danger, their absence does not always represent safety. An obstinate cough, with scanty or difficult expectoration, is an unfavourable symptom, both because it indicates that there is no vicarious relief from the bronchial mucous membrane, and because the very exertion of coughing never fails to aggravate the disease and wear the strength. The character of the expectoration is one of the most valuable indices which we possess for the estimation of the gravity of a case. In simple pneumonia the viscidity and rusty tinge of the sputa are in exact proportion to the intensity of the inflammation, and their increase in quantity and diminution in tenacity and colour are the common attendants of its resolution. Scantiness or absence of expectoration, when other signs prove the existence of a considerable inflammation, is a bad sign, for the reason before mentioned. Dirty or brown watery sputa, and those containing pus, import great danger, inasmuch as they indicate the probable supervention

of the third stage, and a gangrenous odour generally implies a state of great peril. The indications of the expectoration are rendered less certain when bronchitic or catarrhal disease is combined with the pneumonia; and the same remark may be applied to the complication with phthisis. The sudden suppression of expectoration is generally an unfavourable symptom; it is peculiarly so when auscultation discovers a general mucous rhonchus in the chest, because it proves that the muscular powers are inadequate to expel the accumulating matter from the bronchial tubes; and a suppressed secretion of sputa, unless it is the obvious result of a diminution of the inflammation, generally tends to increase it. Pneumonia is frequently resolved without any increase of the expectoration; but when this increase does occur, it always has a favourable influence, and contributes greatly to the cure. A dry harsh state of the skin often attends bad cases complicated with gastric disease, with a loaded parched tongue, great thirst or sickness, and tenderness of the epigastrium. A moderately perspirable skin is the most favourable state; profuse perspirations sometimes occur in fatal cases. The same has been remarked of diarrhœa; yet, as we have before mentioned, both these discharges occasionally prove critical; it is expedient therefore to hold in view, what we have before suggested, that they are to be considered as critical only when they accompany a manifest improvement in the other symptoms. A copious deposit in the urine may generally be viewed as a favourable sign; and the observation of Hippocrates seems to be commonly true, that if, after having been turbid, the urine becomes clear before the fourth day of the inflammation, a fatal tendency may be apprehended. Delirium is generally considered to be a symptom of great danger, and it is the more so when it is constant, and not merely the temporary effect of the nightly febrile exacerbations; but in hysterical females it is often the effect of the treatment, and portends no evil. A comatose or lethargic state is an equally fearful case, as it shows that the functional disorder has already greatly encroached on that strength which is required to bear the treatment necessary for the reduction of the inflammation. The continuance of the various symptoms of inflammation without abatement, notwithstanding the administration of the proper remedies, is always a just reason for apprehension as to the issue.

[Statistical investigation has shown, that pneumonia proves fatal in an increasing proportion after the 20th year, infancy being excepted. Chomel (art. *Pneumonie, in Dict. de Méd.* xxv. 200, Paris, 1842,) found the mortality of persons below 20 to be, at the Hôtel Dieu, in a period of ten years, from 1832 to 1842, in persons from 15 to 20 years of age, 2 in 59, and in both of the fatal cases the individuals were enfeebled by anterior diseases; but between 20 and 40 it rose to 1 in 8; and between 40 and 60 to 1 in 5. It would seem that females are much less favourable subjects for the disease than males,—the mortality in the former being, in the experience of M. Grisolle, (*Op. cit.*) from one-third to one-half greater.]

IV.—Treatment of Pneumonia.

In our examination of the pathology of this disease we found ample proofs that it is an inflammation largely affecting the system of blood-vessels, and that, whatever share nervous irritation may have in exciting or supporting it, these vessels are its peculiar seat, and through them is produced its peculiar mischief. We have moreover seen that in the greater number of cases a congested state of these vessels is the immediate effect of the application of the exciting cause, and precedes that complication of nervous and vascular motions which constitutes reaction and inflammation: we have likewise had many occasions to perceive the serious relations which the disease when formed bears to the two functions most essential to life, respiration and circulation; and the result of all these investigations is to lead us rationally to the recommendation of that mode of practice which the experience of ages has already sanctioned. Pneumonia in its acute form may be called an exquisite type of inflammation, and it is, more than most other inflammations, the proper object for those measures which are called antiphlogistic, and of which bloodletting is the chief. The treatment of other inflammations may require modifications and qualifications because the vessels which they affect may be related to a secretory function, or they may be small and unimportant, or there may be more of nervous irritation than of vascular orgasm, or there may be a coexisting depressing influence in the system; and thus it is that in inflammations of the mucous membranes, of glands, of cutaneous and muscular tissue, of tendons, fasciæ, and nerves, and, in some cases, of serous membranes, bloodletting is less effectual, and requires more limitation than in the disease which we are now considering. This measure, it is true, is not all-powerful in pneumonia, but there are few practitioners who do not admit it to be by far the most important in the early stages: we shall see the limits of its efficacy in rationally examining the subject. Every one who has studied the phenomena of inflammation must be aware that they do not depend entirely on the quantity of blood in the system; and although we greatly reduce this, we may still leave unaffected the state of the inflamed vessels, which remains as a present cause of disorder to the function of the part, and the focus of a speedy return of inflammatory reaction. This may be said of pneumonia even in the first stage; but the second is obviously still less under the control of bloodletting, which, although it may act favourably in preventing an increase of inflammation and in reducing the mass of fluid to pass through the disabled organ, has little or no effect on the solid effusion which now constitutes the organic mischief. Here, then, we have to seek for other remedies to aid the operation of bloodletting, and to resort to where its beneficial operation ceases; and it is an advantage, which modern medicine has to boast of, that it does possess means which are of considerable efficacy in fulfilling these intentions. We are not sufficiently assured of the mode of operation of some of these remedies to be able to class them with certainty as fulfilling specific therapeutic indications, and we shall therefore act more safely by adopting a more empirical course; first describing them under their respective names, and afterwards considering their com-

bined application in the treatment of individual cases.

Bloodletting.—Almost all medical writers, ancient and modern, concur in their testimony as to the advantages of this measure in pneumonia; so that even Laennec, who depended on it much less implicitly than most others, said that "its employment had been proscribed only by some few theorists and medical heretics." (Dr. Forbes's translation, second edit. p. 244.) But there is a considerable diversity of opinion as to the extent to which it ought to be carried, the period of the disease during which it is beneficial, and the best method of practising it. Many ancient physicians, and Galen among the number, recommended the bleeding in pneumonia to be carried to syncope, whatever be the period of the disease; and this practice has been followed by many of the present day, especially in this country. Cullen advises that blood be drawn either until there be remission of the pain and relief of the respiration, or, if these do not appear, until symptoms of a commencing syncope come on. This, we believe, is the plan most commonly pursued in this country, and at this first bleeding a quantity varying from sixteen to forty ounces of blood may be taken before either of these effects is produced. By some practitioners a much larger quantity has been taken without inducing syncope, even to the amount of seventy or eighty ounces; but we consider it doubtful whether it is ever advisable to exceed the highest quantity before stated. Cullen observes that a first bleeding, however large, will seldom prove a cure of the disease, and as the pain and other symptoms recur, the measure must be repeated, even in the course of the same day, to as full an extent as before; and although its greatest efficacy is in the first three days, this recurrence will make a repetition of the measure proper at any period of the disease, especially within the first fortnight. With this practice may be contrasted that of many continental physicians, who never take more than twelve or sixteen ounces daily, and limit the bleeding to the first two or three days, under the apprehension that larger and later depletions interfere with the natural crisis of the disease. We even find Pinel and Brichetau strongly deprecating the free use of the lancet, and inculcating the precepts of Hippocrates, Stahl, Boerhaave, and Van Swieten, to treat mild peripneumonies only by diluents, expectorants, fomentations, pediluvia, and abstinence; and declaring that one or two bleedings at the commencement are all that are generally useful in the severer cases. It is a satisfactory proof of the superiority of the English method of practice to find that the best authorities in France now advocate free depletions much more than formerly. Andral and Chomel recommend bloodletting to sixteen or twenty ounces, practised, if necessary, two or three times a day during the first days of the disease, and more moderately afterwards. Some of their countrymen still more recently have prescribed two or three pounds to be drawn every twelve hours at the commencement of the inflammation, and if the dyspnœa continues, eight to twelve ounces daily afterwards. We may remark, as a partial excuse for the tardy adoption of these more energetic measures by continental practitioners, that probably many of the *mild peripneumonies*, described formerly as cured without bleeding, were in reality cases of bronchitis, and that an improved pathology and method of diagnosis have proved to them what pneumonia really requires. We now know fully, and we are indebted principally to our foreign brethren for this knowledge, that pneumonic inflammation tends much more strongly to effusion and disorganization than to resolution; and our study of the pathology has pointed out, in a very striking manner, that the spontaneous relief of an extensive plexus of vessels gorged with blood, and under the immediate influence of an irregularly excited heart, is too improbable an event to be thought of otherwise than as an exception, the general rule being to an increase of the engorgement, and a progressive encroachment on the proper state and office of the organ. Expectant medicine, in such a case, is therefore both irrational and dangerous.

There are, we presume, no practitioners in this country who question the superior utility of free bloodletting, as early as may be after the development of the inflammation; and it is generally admitted that the measure is more effectual when the blood is drawn from as large an orifice and as speedily as possible. The impression on the circulation is thus more readily produced, and at less expense of blood, than where the aperture is small and the detraction more gradual, scantier, and more frequently repeated. With a view to this effect, Aretæus advised that a vein in each arm should be opened simultaneously, and this plan was adopted by Huxham and Husson. There is, however, a limitation to the advantage of this sudden impression on the system; and this limit seems to us to depend on the degree in which the disease has become fixed in the pulmonary vessels. In the first hours of the inflammation such a sudden loss of blood in the semi-erect posture as will make the pulse soft and weak, and induce some feeling of faintness, will often restore the balance of the circulation, and enable the inflamed vessels to recover their wonted calibre; so that, although some general reaction follows the approach to syncope, the seat of the disease does not suffer from its effects. But if the inflammation has subsisted longer, the inflammation is rarely thus cured by a single bleeding; the vessels of the lungs remain distended although syncope be induced, the depressing effect of the depletion is of short continuance, and the returning reaction brings back the inflammation in its former character. On this account, when the inflammation has lasted more than twelve hours, we are distrustful of a syncope induced by a small bleeding, and we have generally found it necessary to repeat the venesection sooner and more frequently than where more blood has been drawn at first, and only a tendency to faintness produced. Cullen has justly remarked that many persons faint even upon a small bleeding, and as this may prevent the drawing as much blood at first as a pneumonic inflammation may require, it is the more necessary in these cases to repeat the measure more largely afterwards. Early fainting should therefore be rather avoided than desired, and if the patient feels it approaching when only a few ounces have been extracted, and little relief is manifested in

the symptoms, it is expedient to stop the orifice, and to let the patient lie down for a few minutes, which, with the aid of a little cold water and a smelling-bottle, will restore the circulation to a state in which it will bear the necessary depletion. The quantity to be drawn may vary in different adult subjects according to the age, constitution, extent of the inflammation, &c., from twenty to forty ounces. If it is known that the patient bears bleeding well, the larger the orifice and the speedier the loss of blood the better; but nervous subjects, and those liable to palpitation and fainting fits, must be coaxed more gradually to bear a full depletion, and guarded from a fictitious syncope by the horizontal posture. If these precautions are neglected, the disease will continue to gain ground in spite of the apparent impression on the circulation, and each hour lost will diminish the beneficial influence of subsequent depletory measures. Much discretion is required in determining the quantity of blood to be drawn, and this determination can never be satisfactorily made beforehand; within the limits just named, therefore, the immediate effect of the operation is the only sure guide. In the first stage of the inflammation, whilst the crepitant rhonchus prevails, and there is little or no dulness on percussion, bloodletting shows its greatest efficacy, and the more so even when this stage is recent. Hence, as we have already remarked, one full, speedy bleeding of thirty ounces, or thereabout, instituted within the first few hours, will often prove sufficient to destroy the orgasm, and relieve entirely the dyspnœa and pain; the remaining quickness of pulse and cough yield to subsequent milder treatment; and the knowledge of its superior efficacy at this time may authorize us to carry the depletion beyond the point of producing relief to the symptoms, and even to the verge of syncope. After the first twelve hours have elapsed, and when the stethoscope discovers no remains of respiratory murmur mixed with the crepitant rhonchus of the affected part, there is little chance that a single bleeding will prove sufficient; and although, when well borne, it may be carried to forty ounces, more regard must be paid to avoid syncope than in the first instance. This is the more necessary when the crepitant rhonchus is on the decline and becomes mixed with bronchophony, and the part sounds dull on percussion, signs which prove the transition to the second stage. As this becomes formed, as the disease obtains a physical hold of the part, full and sudden impressions on the circulation lose much of their beneficial influence; and they are to be sought for only when the first stage of inflammation still prevails and spreads in another part of the pulmonary tissue. If we are called to a patient with a lung already hepatized, and on whom bloodletting has not yet been practised, it is generally advisable to bleed, but not with an expectation of complete relief to the symptoms, or with a view to reduce the pulse; the solid effusion constitutes a material cause of the dyspnœa, which no bleeding can remove; and the heart, although sometimes quieted by diminishing the load which it has to propel through an obstructed organ, often becomes more irritable, and rises both in force and in frequency. If the bleeding is carried to syncope at this stage, it is commonly succeeded by a reaction, which aggravates the dyspnœa and adds to the disorder of the hurried circulation. Bloodletting is not the chief remedy in this stage, and, even where used for the first time, it should be restricted to the object of aiding other measures, and not pushed to the length of inducing syncope.

All the advocates of bleeding in pneumonia admit the necessity of repeating the measure in case of the continuance or recurrence of the symptoms of inflammation, and it is in the steady and discreet perseverance in this measure, notwithstanding a variety of phenomena which may seem to oppose it, that the scientific and experienced physician shows his skill and proper firmness. The temporary relief afforded by the first bleeding may have given place to an aggravated dyspnœa, and the pulse may have become weak, contracted, and very quick; symptoms of great debility may have shown themselves; and the patient may express feelings of faintness and exhaustion, which seem to be further evinced by his indisposition to any exertion or movement unconnected with his efforts to breathe. This array of discouraging indications deters the timid practitioner from again resorting to the lancet, and he finds in certain authors a sanction for a supine course, in their cautions, that if the bleeding be pushed far, the disease will become typhoid, the expectoration arrested, and the frame thrown into a state of hopeless debility. As long, however, as the physical symptoms indicate the continuance of the first stage of inflammation, except in a few cases to be presently noticed, there should be no hesitation freely to repeat the bloodletting any number of times until the symptoms are relieved; and it has been proved by ample experience that this treatment, instead of giving rise to a typhoid state, and facilitating effusion, prevents these events by arresting their real cause, the inflammation and its extensive injury to the respiratory function. These are far more formidable and deadly than the consequences of even an immoderate loss of blood, and we can add our testimony to that of Dr. Mackintosh when, after cautioning against excess in the use of this measure, he says, "nevertheless I am persuaded from experience in treating the disease, and from examinations after death, that much more mischief is done by bleeding too little than by bleeding too much." (Practice of Physic, vol. ii. p. 424.) It is the delay or insufficient application of this measure at first, that often throws the disease into that apparently typhoid form which has deceived so many as to its real cause; and nothing but the actual experience that the pulse frequently rises in force and fulness, the breathing becomes easier, the lethargy or sinking and the anxiety of the countenance become diminished, and the strength increased, as the pernicious oppression of the respiration is relieved by repeated bleedings, can impress the mind fully with the safety and expediency of the measure. "How often," says Andral, "have we not seen bloodletting employed with the greatest advantage in individuals in whom the pulse was small and contracted, the face pale, the extremities nearly cold, the general debility

apparently very great, but in whom at the same time the respiration was greatly oppressed." (Clin. Méd. t. ii. p. 380.)

We do not maintain that there are no cases in which the disease is from the beginning connected with a truly adynamic form of fever, and in which bleeding, even to a small extent, and however carefully managed, causes faintness without relief. This occurs sometimes in those whose vascular system has been greatly debilitated by excess in ardent liquors, and in those of a strongly scorbutic diathesis; it sometimes prevails epidemically at the same time as other typhous diseases, and changes the character of the peripneumonies that may then happen to prevail. It may be almost a question whether in these cases the local disease in the lungs is not rather a congestion of blood in an altered state than an inflammation, and it is very commonly the sequel rather than the cause of the fever. At all events, the impropriety of the free use of bloodletting is obvious from its effects, and our chief reliance must be on other measures.

With regard to the time in which it will become proper to repeat the measure, much will depend on the severity of the case and the success and extent of the first bleeding. If this was copious, and produced signal relief to the dyspnœa and pain, its full effect will not be apparent for four or five hours, during which time further benefit may follow from the use of other remedies; at the end of that time the patient should be seen again, and if he should be found still to suffer, and especially if there have been any increase of dyspnœa, the bleeding must be repeated with freedom, either until some relief be manifest, or till an impression be produced on the circulation. If the first bleeding failed from the speedy supervention of syncope before much blood was drawn, it will be necessary to repeat the visit in an hour or two, and again to make trial of the measure, when the patient will often be found to bear a much larger bleeding than at first, and with proportionate and more permanent relief to the symptoms. The pulse furnishes a much less certain indication for the use of the lancet than the state of the breathing, which is the function which we should be most anxious to relieve. In the first stage it rarely happens that bleeding will not produce some immediate relief of this kind as well as of the attendant pain, and this effect may generally guide us in the extent to which we may carry the measure. If, however, although the bleeding seems little affected, during the flow of the blood at this repetition of the practice the pulse becomes very weak, quick, and running, it is expedient to stop the bleeding and trust to local depletion and other remedies. It cannot be denied that this intolerance of bleeding shows itself in some rare instances from the very commencement of the disease, giving to it the real typhoid type; this character, however, has been ascribed to a greater number of cases than deserve it, and we cannot be too careful in our endeavour to distinguish the real from the false cases of vascular debility: the distinction can seldom be so satisfactorily made as by the cautious trial of venesection itself. Laennec has, it is true, pointed out one test, which is sometimes of great use and certainty, in the state of the action of the heart as investigated by the stethoscope; when, amidst symptoms of general debility, the pulsations of the heart are heard and felt more strongly in proportion than the arterial pulse which they not unfrequently are, especially under the sternum, there can be no fear of bleeding, however weak the pulse may seem; but if they are both weak, the detraction of blood will almost always occasion complete prostration of strength. (Op. cit. p. 249.) There is an exception to this rule in the complication with hypertrophy of the heart, in which the pulsations continue to be apparently strong when the circulation is really very weak. The palpitation of reaction after loss of blood in nervous subjects may likewise be mistaken for the strong pulsations of Laennec; and this error is the more to be avoided as this reaction often accompanies a state of the circulation which will not bear bloodletting.* A good auscultator may distinguish the palpitation of reaction by its louder sound and more abrupt but less forcible impulse than those attending the really sthenic pulsations of the heart; but some experience in auscultation is required to make this distinction available in practice. Although, therefore, this test is very useful in deterring us from venesection in some cases of real debility, yet where it seems to indicate the use of this measure, it must not make us neglect the careful study of the effects as the blood flows from the vein.

In the second stage of inflammation, when dulness on percussion and the absence or the bronchial character of the sound of respiration indicate hepatization of the lung, bloodletting loses that efficacy which entitles it to the foremost place in the remedies for pneumonia. Some writers, indeed, proscribe its use at this period, as injurious and interfering with the curative process. The ancient physicians generally renounced bleeding after the fifth day if the expectoration was abundant, for fear of checking it, and their caution was followed by most practitioners until the end of the last century. We can readily perceive that the efficacy of bloodletting must be very much abridged by the permanent form which a solid interstitial effusion has now given to the organic disease, and therefore it is no longer to be expected that its repetition, however copious or frequent, can at once remove the dyspnœa or lower the pulse; but in a more moderate degree it is still useful, inasmuch as it reduces the quantity of blood which is to pass through the lungs, and tends to prevent the progress of the inflammation to the third and more hopeless state, purulent infiltration. We find, accordingly, many excellent practical writers, Stoll, Cullen, Frank, De Haen, Andral, Chomel, and even Laennec, recommend the repetition of venesection during the second and even the third stage, whenever the state of the breathing, the pain, or the fever seem to require it. Laennec thought that to bleed to syncope might produce the evil effect of checking the

* In hysterical females especially, this and other symptoms of nervous excitement, as pain, delirium, and convulsions, often occur and deceive the unwary as to their real cause; they are not dependent on the disease, but on the loss of blood, and belonging to the class of irritations of reaction, require sedatives rather than further depletory measures. (See IRRITATION.)

expectoration, apprehended by former writers, and in this opinion our own experience disposes us to coincide. If venesection has been freely practised before, the occasional loss of eight or ten ounces from the arm, conjoined with local depletions, is generally as much as is borne well or proves useful, and the further relief of the disease must be left to other means. In some instances this quantity may be exceeded with advantage, even at this period, when the stethoscope discovers the development of inflammation in a new part. If, likewise, bleeding has been neglected, or only sparingly used before, a larger abstraction is often serviceable, even in the second stage, to remove that relative plethora into which the obstructed state of the lungs converts the ordinary fulness of the vascular system, and hence the great relief that even at this period general bloodletting sometimes affords. Here, it may be perceived, there is no reason for a large orifice or a speedy abstraction of blood, and these should be the rather avoided, as the syncope which they may induce is not a desirable event.

[It is maintained by M. Louis, (*Researches on the Effects of Bloodletting in some Inflammatory Diseases*, &c., Boston 1836,) from the results of numerical observations, that the influence of bleeding, when performed even within the first two days of pneumonia, is less than has been supposed, and that in general its power is very limited; that its effect, however, on the progress of the disease is found to be happy, and that patients who were bled during the first four days recovered—other things being equal—four or five days sooner than those bled at a later period. The researches of M. Louis gave occasion to numerical investigations, as to the effect of bloodletting in pneumonia on this side of the Atlantic. (Dr. James Jackson, in *Translation of Louis on Bloodletting*, cited above.) Of 31 cases, treated at the Massachusetts General Hospital, in three, bloodletting was practised on the first day of the disease. The average duration was $13\frac{1}{3}$ days. The number of bleedings in each case was four; and the average quantity of blood, abstracted in each, $61\frac{1}{3}$ ounces. In 15 cases, which were bled for the first time, on the first, second, or third day, the average duration was $12\frac{1}{3}$ days. The same thing was true, with a slight difference, of 21 cases in which bleeding was practised on or before the fourth day. In five cases bled for the first time after the fourth day, the average period of convalescence was $13\frac{1}{5}$ days. In these 26 cases, the average duration of the disease was $12\frac{1}{3}$ days. In five cases, bloodletting was not employed, except in one in which six leeches were applied. The mean duration of the disease was $14\frac{3}{5}$ days. So far, therefore, as these cases go, it would seem that the effect of bleeding, on or before the fourth day of pneumonia, is to shorten its course nearly one day, when compared with the cases in which it was not employed until after that period. Compared with those who were not bled, it was shortened a little more than $2\frac{1}{4}$ days. These results are certainly confirmatory of those of M. Louis, which led him to infer, that bleeding does not exert so powerful an effect on pneumonia as is generally believed; but they are not sufficient to induce us to discard this important remedy, or to place as little reliance upon it as has been done by some. It is questionable whether it ever succeeds in cutting the disease short. The remarks of M. Louis on this point are very explicit. His conclusion is;—"that we cannot cut short pneumonia by bloodletting, at least during the first days of the disease." It must be admitted, however, from the testimony of most observers, that in strong and vigorous subjects, general bleeding is an important remedy; yet it must be equally admitted, from the same testimony, that it ought not to be practised at all periods; and that after the stage of engorgement has passed into that of solidification, and, *à fortiori*, when it has entered that of interstitial suppuration, it may be a very questionable or improper agent. When the practitioner is called early, a copious bleeding, which exhibits its effects upon the morbid manifestations, but short of inducing syncope, may be sufficient. One single venesection of this kind, carried to the extent of relieving the pain in the chest, of permitting the patient to take in a deep inspiration, and of converting the small, rapid and oppressed pulse into one that is large and full—has been found more efficacious than four practised at a later period. In 180 cases, according to Dr. Most, (art. PNEUMONIA, in *Encyclop. der Gesammt. Medicin. und Chirurg. Praxis*,) it was found necessary in two only to repeat the bloodletting on the same day, or at the next exacerbation. Dr. Stokes, too, states, (*On Diseases of the Chest*, 2d Amer. edit. p. 307, Philad. 1844,) that he has found the bold and repeated use of the lancet to be unnecessary, and he is convinced, that, in general, a single bleeding, or at the most, two bleedings will be sufficient. Out of many hundred cases he has had only one in which it was necessary to bleed oftener than twice: in that instance, there was hypertrophy of the heart.]

We have said nothing respecting the buffy coat of the blood as a criterion of the propriety of venesection, because we have not observed any constant relation between this sign and the intensity or even the existence of inflammation. When the crassamentum is buffed, cupped, and firm, early in the disease, it may confirm us in persevering in the measure; but in the after stages, the separation of the fibrine from the colouring matter may proceed as much from irritation or the use of mercury as from inflammation, and it is at this time only that its indications are wanted.

Local bloodletting.—It is obvious that, in the greater number of cases, the abstraction of blood from the integuments of the chest can produce but little impression on a disease that occupies so considerable a portion of the vascular system as that extensive tree of vessels which conducts the smaller circulation; and accordingly local depletion is but a subordinate measure in the treatment of pneumonia. [Dr. Stokes, however, (*Op. cit.*) considers it the principal remedy.] Many practitioners, however, often employ leeches or cupping as subsidiary to phlebotomy at the commencement of the disease. Thus Andral tells us that Lerminier often ordered the painful side to be covered with leeches during the flow of blood from the vein. This method, it may be remarked, is better adapted to an hospital, where there are plenty of experienced assistants, than to private

practice, where one of these operations is enough at a time: but we have found great advantage in prescribing local bloodletting in the space of an hour after general, especially where a stitch in the side indicated the extension of the inflammation to the pleura. From twenty to forty leeches followed by a large cataplasm, or from ten to sixteen ounces of blood drawn by cupping, often not only have the effect of relieving a pain which greatly aggravates the difficulty of breathing and cough, but also in some degree prolong the depression resulting from the general depletion, and prevent the bad effects of a reaction which sometimes succeeds to this depression. In aged and exhausted subjects, and in those cases of real adynamic pneumonia which do not bear venesection, this local bloodletting becomes a principal remedy, and although much inferior in efficacy, and less worthy of our confidence, it must often be our resource when the strength would sink under general depletions. In infants the bleeding from leech-bites is equivalent to a general bloodletting, and below the age of two years is very commonly substituted for it. It may be suggested, however, that about and above this age, when, in the early stage of the inflammation, the symptoms are pressing, it is better to use venesection; and if there should be any difficulty in bleeding from the arm, from four to eight ounces may be taken from the jugular vein with great advantage; but if depletion be again necessary, that by leeches will be generally sufficient. It is sometimes recommended to apply a leech or leeches to the foot or arm of infants, suffering under inflammatory diseases, because the bleeding can better be controlled in those parts; but the greater benefit produced by the depletion near the affected organ leads us to apply them in preference close to the sternum, or under the clavicle of the affected side; we have never experienced any difficulty, when it became necessary, in stopping the hemorrhage by a compress and bandage or slips of adhesive plaster. In adults, when leeches are used as local depletories, the intercostal spaces nearest to the point of pain are the best place of application; for contiguity, independently of vascular communication, affects the removal as well as the propagation of inflammation.

In the second and third stages of pneumonia local bloodletting may sometimes be substituted for venesection, on any return of pain or slight increase of dyspnœa which seems to demand more immediate relief than can be obtained from the internal remedies or blisters. In slight limited inflammations, such as those attacking phthisical subjects, it is often the only kind of bloodletting that is necessary.

Tartar-emetic.—Next to bloodletting this remedy is perhaps the most powerful that we can employ for the cure of acute pulmonary inflammation. Its utility in emetic and in nauseating doses had long recommended it in pectoral complaints, but its power of subduing acute inflammations independently of its emetic, nauseating, or diaphoretic effects, has been only of late years developed. Rasori of Genoa was the first who established it,* and besides the testimony of many of his own countrymen in its favour, it has received the highest and most unqualified praise from the illustrious Laennec, whose sanction, after the great light which his labours have thrown on the pathology of this disease, cannot but command our attention. Although it may fall short of the sanguine hopes held out by the advocates of this practice abroad, the experience of many distinguished physicians in this country tells much in its favour, and we believe justifies the opinion expressed at the beginning of this paragraph. The success which has attended the treatment of peripneumony by repeated emetics, as recommended by Riverius and Stoll, probably in part depended on this peculiar action of tartar-emetic; under this practice in the hands of Dr. Hellis of Rouen, and some others in France, the proportion of deaths was considerably less than usual, not exceeding one in nine; while the average mortality of the disease, when treated by bloodletting and derivatives, amounts to one in six or eight, (*Laennec*, p. 261); and in hospital practice, and among the lower ranks, it is often greater. The efficacy of the emetic treatment in croup, advised by Dr. Cheyne, and in ophthalmia and in hernia humoralis, probably partakes of the same principle, and is less dependent on the emetic than on the *contro-stimulant* or *anti-inflammatory* effect of the tartarized antimony. As the subject of large doses of tartar-emetic has been already described in the article Inflammation, we shall here only speak of its application in the treatment of pneumonia.

Rasori, with whom the regular introduction of this practice commenced as long ago as the year 1808, gave the medicine in the following manner. Usually after one or more bleedings, but sometimes without this measure, from twelve to twenty-four grains, or in severe and advanced cases, from a scruple to half a drachm were given during the day, and the same repeated in the night; these doses were daily increased until they amounted to a drachm or several drachms in the twenty-four hours. The result of this extraordinary practice was, that out of 832 cases of pneumonia 173 died. Out of 115 cases treated in the same way by Tomassini of Bologna, only 14 died; and several other equally favourable reports are made by other physicians of Italy. There are, however, counter-

* Although we yield thus much to a foreigner, we must not pass over a just claim to priority in *practice* in favour of Dr. Marryat of Bristol, who died in 1793. In the last edition of his "Therapeutics," published in 1790, is the following passage, in which both the febrifuge virtue of tartar-emetic, and the *tolerance* of the system in regard to it are described. "Any fever may be soon extinguished by the use of the following powders:—Take of tartarized antimony five grains, white sugar (or nitre) a drachm; let them be well rubbed in a glass mortar, and divided into six powders; one to be taken every three hours, notwithstanding the nausea the first may possibly occasion. If these are taken, (which is commonly the case) without any manifest inconvenience, let there be seven grains in the next six powders; and in the next ten. Here I beg to retract what I said in some former edition of this work, viz. that till sickness and vomiting were excited, this noble medicine was not to be depended upon. For I have since seen many instances wherein a paper has been given every three hours, (of which there have been ten grains in six powders,) without the least sensible operation, either by sickness, stool, sweat or urine, and though the patients had been unremittingly delirious for more than a week, with subsultus tendinum and all the appearances of hastening death, they have perfectly recovered without any medical aid, a clyster every other day excepted. I have lately seen a great many cases similar to the above, and the tartarized antimony has invariably produced the same effect."—See Medico-Chirurg. Review, No. 31. p. 253.
